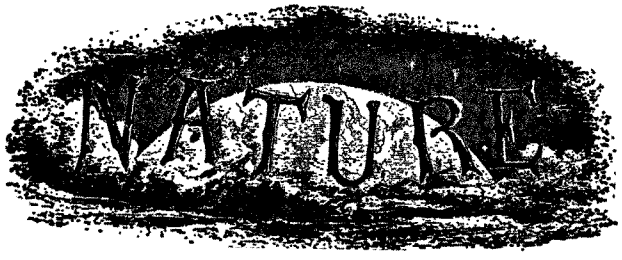
THE latest annual report of the Food and Agriculture Organization of the United Nations (see page 1021) is a more realistic document than many previous members of the series. Sensibly enough, the report openly acknowledges that there has been a sustained increase of food production in the past few years. "At long last something of a turning point may have been reached in the difficult struggle of the developing countries to achieve a sufficiently rapid increase in their food production." In the past, the temptation to urge on readers the danger of the still growing population of the Earth has often been too strong for the authors of these reports. Now, however, it does seem clear that when seasonal ups and downs are ironed out, food production is increasing if anything more quickly than population. For the world as a whole, for example, food production per head is now about 10 per cent greater than in the early fifties and, as the annual report of the FAO makes plain, the improvement in the Far East has been particularly marked—a total increase of 14 per cent in three years. Although the new cereals are a part of the explanation, there is no doubt that much of the improvement can be attributed to the increasingly level-headed ways in which agriculture is managed in developing countries. Although the credit must largely go to the governments concerned, there is no doubt that the FAO itself deserves some share of it.

If the statistics of food production for the world as a whole are satisfactory, however, there still remains the problem that the effects of the new agricultural revolution vary enormously from one place to another. In both the Far East and the Near East, food production is gaining on population, but the balance is stagnant in Latin America while in Africa the trend is downwards, chiefly because of decreases of cereal production in north-west Africa. Elsewhere, luckily, the FAO considers that the livestock industries are growing well and that modern agricultural technology, is catching on. Obviously it is a great help to most of the developing nations of Africa that the level of economic activity is growing much more quickly than the population, so that there is cash to spare to the support of mechanization in agriculture. In the long run, this is the way in which these nations will find a way out of their immediate difficulties.

But what of the more distant future? The most obvious danger is that there may in due course be such a large increase of population that no amount of increased efficiency in agriculture will be able to provide for it. This, however, is still very much an academic matter. For one thing, the way in which the graphs of population and food production have kept more or less in step for the past thirty years suggests that demand can effectively stimulate supply without bumping up against physical limitations of an absolute character. Second, the population statistics on which these calculations are inevitably based take very little account of the way in which the birthrate has been declining in several countries in the past few years.



Aircraft in Trouble

THIS has been a bad week for new aircraft projects. In the United States, Congress has for the time being at least decided not to vote the funds to keep the Boeing design for a supersonic transport (the SST) alive for another year (until July). In Britain, the government has decided (see page 1019) to provide no further support for two dreams prevalent among British aircraft manufacturers for several years—the scheme for participating in an airbus designed by a European consortium and one for building an almost identical vehicle in Britain. By this act of seeming brutality, the government will have gone a long way to finish off the European airbus and at the same time to ensure that the British aircraft industry will never again become a builder of air frames in the grand manner. Almost inevitably, European airlines wishing to equip themselves with large passenger aircraft for the late seventies will have to buy instead in the United States, while the chances are high that if the European airbus does survive, this will be dependent on American and not British engines. In the United States, the boot is on the other foot, for it now seems probable that if Concorde can be made to function properly, American airlines will be going cap in hand to the British Aircraft

Corporation and to Sud Aviation for their first examples of supersonic aircraft.

Why should all this be ? With aircraft as with computers and many other modern technical developments, the scale of investment needed to bring a product to the market place is at once beyond the resources of nationally based commercial enterprises and also too great to be recouped by sales within a restricted market. Nobody should be surprised that in circumstances like these there is a fierce conflict between patriotic sentiments about the need to manufacture each product of innovation on a national basis and the need somehow to make such devices commercially viable. The trouble, of course, is that the governments which pay for these developments are also the sources of the chauvinistic zeal that serves somehow to ensure that they bring no profit. In the long run, devices must be found for making sure that governments do not behave in such a foolish way, which in turn implies that all of them will have to recognize that there is no lasting shame in having to buy capital equipment from elsewhere. With a little luck, the sober lessons of this week's decisions about new aircraft may persuade two of the governments concerned that the time has come to learn a little moderation.

100 Years Ago

AT the meeting of the Royal Geographical Society, held on Nov. 29, a paper was read "On the Geography of the Sea Bed," by Capt. Sherard Osborn, R.N. The author gave an account of our present knowledge of the configuration of the bed of the ocean, as derived from Admiralty surveys and submarine telegraph expeditions during the last fifteen years. His explanations were illustrated by a number of diagrams showing sections of the North Atlantic and other oceans. It has been definitely ascertained that the greatest depth of the ocean does not reach 3,000 fathoms in any part where telegraphic lines have been laid. The bed of the North Atlantic consists of two valleys, the eastern extending from 10° to 30°, the Western from 30° to 50° West longitude. The extreme depth of the eastern valley is under 13,000 feet, which is less than the altitude of Monte Rosa. This valley has been traced southward to the equator. It is separated from the western valley by a ridge in 30° West long., in which the average depth is only 1,600 fathoms. This ridge terminates to the north in Iceland, and southward at the Azores, so that it is volcanic in its character at both extremities. Its extreme breadth appears to be under 500 miles, and the Atlantic deepens from it on both sides. Explorations carried on in the Mediterranean, the Red Sea, and the Indian Ocean, showed similar uniformity in the level of the sea-bottom ; and the general conclusions arrived at by Capt. Osborn were that in the deep sea there is an absence of bare rock, and that there are no rough ridges, canons, or abrupt chasms.

OLD WORLD

FRANCE

Space Effort Declines

AFTER ten years of expansion, the Centre National d'Etudes Spatiales—the French Space Agency—is being forced to take in its belt. Although some decrease in the agency's budget was to be expected following the devaluation of the franc in 1969, the drop of more than 20 per cent last year cannot be attributed solely to the state of the French economy. It is true that the series of satellite launchings from French Guinea with the Diamand-B rocket is keeping up to schedule and that the plans for meteorological satellites in the Éole and Météosat projects will ensure that the French space effort has a clear identity well into the nineteen seventies. But the damaging two month strike of engineers and technicians (which ended last month) at the CNES site at Brétigny, the nerve centre of the space programme, has highlighted the uncertainty surrounding the long term future of the CNES and has reinforced doubts about the correctness of the balance between national and international projects for which France has opted in its space policy.

The importance of ensuring that the French space programme fits sensibly into a wider European framework is a dominant theme in the annual report of the CNES up to July 1970. The report points out, for example, that from 1971 about 40 per cent of the cost of the launching site at Kourou in French Guinea will be met by ELDO, and it also draws attention to the agreement concluded this year to launch two models of the Franco-German telecommunications satellite, Symphonie, by the end of 1973.

Development of a series of French meteorological satellites under programmes known as Éole and Météosat is also given prominence in the report. The first satellite, Péole, is scheduled to be launched later this month into an equatorial geocentric orbit and will be followed by a second satellite, Éole, in July 1971. These will carry out preliminary studies to pave the way for a detailed survey of cloud cover in the visible and infrared wavelengths in a later project, Météosat. The Météosat satellite will also be launched into an equatorial orbit and will provide data on the western regions of Europe, on France and on Africa and Madagascar. The programme will fit into the Global Atmospheric Research Program (GARP) and it is likely to complement the European plan for putting a meteorological satellite into polar orbit.

The next satellite in the D-2 series, designed essentially for research in astronomy, is the D-2A which will be put into orbit in 1971 with five experiments to study the ultraviolet emission from the Sun and the distribution of hydrogen in the Earth's atmosphere. D-2B will follow in 1973 and will house experiments from the Space Laboratory in Marseilles and the Laboratory of Stellar and Interplanetary Physics of the CNES to study solar and stellar emissions in the far ultraviolet. The report also points out that French rocket probes should remain competitive for astronomy research for about five more years, and will be developed under the programme name FAUST.

The impending transfer of various facilities of the CNES from Brétigny near Paris to Toulouse was one of the principal bones of contention in the recent strike at Brétigny. The division of rocket probes is now being transferred and the installation of a space simulator at Toulouse is nearing completion. But the transfer of satellite work, planned for 1971–2, has now been postponed in deference to the views of personnel and there is concern at the probable lull in activity towards the end of 1971 after the D-2 and Éole satellites have been finished and before the new programme has got under way.

CERN ACCELERATOR

Green Light at Last

THE British government's decision to participate in construction of the 300 GeV proton accelerator at CERN makes it almost certain that after more than two years of oscillating fortunes, the project will finally go ahead. A formal decision must await the meeting of the CERN Council in Geneva on December 22, but the governments of the three other major contributors, West Germany, France and Italy, have already made it clear that they are ready to join the project if the British government also gives its support. The decision to participate, announced last week by Mrs Thatcher, Secretary of State for Education and Science, reverses a decision taken by the Labour government in 1968 not to back the original version of the project, which would have cost more than half as much again as the £90 million estimated for the new version. The original scheme is also now recognized to have been too inflexible to make the best use of possible developments in magnet technology during the coming decade.

The timing of Mrs Thatcher's announcement is itself significant. With more than two weeks still to go before the governments of the other eleven member countries of CERN are obliged to make their final decisions on the project, the British government has calculated that an early decision on its part would provide a firm stimulus for the other governments to add their support to the project before the meeting of the CERN Council. Officials at CERN are particularly pleased with the swiftness of the decision. The debate on the project in the Swedish parliament is also being watched with particular interest from Geneva. Although the Swedish contribution would amount to only 4·6 per cent of the total cost it is felt that the attitudes of the smaller countries are likely to be reflected in the Swedish debate.

The British government's decision will have a profound influence on nuclear physics in Britain. The £2·5 million a year which Britain will contribute to the 300 GeV accelerator will be taken from the existing nuclear physics budget of the Science Research Council, which stands at about £20 million a year. Because £7 million of this is already earmarked for the existing programme at CERN, the extra money must come from the £13 million which is shared between the Rutherford and Daresbury laboratories and the universities. The question of how best to initiate cuts in the national programme will be discussed at the next meeting of the nuclear physics board of the SRC, scheduled to take place on December 22 but now postponed because of the council meeting at CERN.

SELENOLOGY

Shedding Light on the Moon

Paris, December.

THE French laser reflector carried to the Moon by Luna 17 had its origin in a visit to the Soviet Union by General De Gaulle in 1966, when a Franco-Soviet committee was established to organize scientific cooperation. France had then just undertaken a series of laser ranging experiments with its Diadème satellite. The Russians, who were considering lunar experiments along the same lines, asked the French to participate and build a reflector. In February 1968, the arrangement was made formal by a Franco-Soviet agreement and the Centre National d'Études Spatiales (CNES), the French co-ordinating agency, awarded the contract for the construction of the unit to Sud Aviation (now known as Société National Industrielle Aerospatiale).

The list of experiments planned for these reflectors is already long and includes measurements of the distance between the Earth and the Moon, of the Moon's radius to within 50 metres (instead of the present two kilometres), of the physical librations of the Earth and Moon, a study of fluctuations in the rotation rate of the Earth, and more accurate measurements of distance between points on the Earth.

It is hoped that these last measurements will provide a direct verification of continental drift, but this calls for a series of measurements extending over several years and to a precision of better than a metre. Another objective is to define more precisely the universal gravitational constant.

Both the American and French reflectors are made up of silica cube corners, the faces of which must be ground to within two-tenths of a second of arc. The French chose a compact array of fourteen prisms, each with a base of ten centimetres, compared with the Apollo 11 reflector made up of one hundred prisms of 3·75 centimetre diameter. Additional silver plating on the reflecting faces of the trihedrals increases their reflecting power. Under comparable conditions the performance should be five times better than that of the Apollo 11 panels. The French device cannot, however, be used during the lunar day because heat expansion deforms its elements, a problem which is less severe for the Americans because of the smaller size of their elements. Thus the French reflector works better than its American counterpart during the lunar night, but cannot be used during lunar daylight. This, of course, increases the problem of pointing the laser accurately at the reflector—the reflector position has to be known with respect to points on the illuminated crescent of the Moon.

Stations involved in the Franco–Soviet experiment so far are the Crimean Observatory and the Pic du Midi Observatory in the Pyrenees. The Pic du Midi team has already experimented with the Apollo 11 reflector. A ruby laser was used to send a series of 25 Joule pulses of one millisecond through a 105 centimetre telescope which reduces beam divergence by a factor of 6 × for a 95 cm exit diameter. A 0·1 Joule/km^2 spot is produced on the Moon. Statistical analysis of 100 shots is required to verify that an echo has been received and to permit a precise measure of the time lapse between transmission and reception (about 2·5 s.) The number of acquisitions should be four times greater with the Luna 17 reflector. It should be noted that one hour is needed to verify echo reception and work is limited

to about 3 h a night, three nights a month if weather conditions are good.

The 2·5 metre telescope of the Crimean observatory can receive more reflected light and its laser is four times more powerful than that of the Pic du Midi. Unfortunately its low altitude site complicates observational work.

In the United States the Lick and McDonald observatories have measured the Earth–Moon distance to within 30 cm. The Orszag team is now building a 10 m^2 light collector which should improve the observations and will be operational by summer.

The United States and USSR are working on hollow corner reflectors which would have lower thermal capacity and thus less thermal deformation.

ROCKETRY

Comecon Lowers its Sights

from our Soviet Correspondent

FOLLOWING the success of the joint effort by the Comecon countries to produce the Interkosmos satellites, the latest Comecon space project may seem unambitious. The Soviet Union and its partners are embarking on a programme of geophysical research using instrument packages launched into ballistic trajectories by non-orbital rockets. According to its publicists, however, the main purpose of Vertikal-1, the first firing in the series which reached an apogee of 487 km before descending to 100 km where the recoverable instrument package was released, is to investigate the atmosphere between 100 and 200 km. The problem in maintaining a satellite in this region is that the atmospheric drag is still sufficiently large for the orbit to be degraded rapidly. Dr I. Zacharov, a Czech scientist writing in *Pravda*, calls this region the "ignorosphere where even the density of the air has not been studied sufficiently".

In the published programme the main purpose of Vertikal-1 was "to carry out complex investigations of the ultraviolet, X-ray and submillimetre radiation from the Sun and the absorption of this radiation in the Earth's atmosphere; determination of the electron concentration and temperature at high altitudes; and studies of meteoritic particles". The instruments include X-ray pinhole cameras and an X-ray spectroheliograph from Poland, X-ray spectrometers from the Soviet Union, equipment for the study of meteoritic particles (jointly developed by the USSR, Czechoslovakia, and Hungary), a Lyman α photometer and r.f. capacity probe from East Germany, and equipment for measuring solar submillimetre radiation and ionospheric parameters (developed by the USSR with help from Bulgaria, East Germany and Czechoslovakia). The flight was also used to measure the absorption of radio waves at frequencies of 1, 1·5 and 2 MHz, using an East German ground unit.

It is worth noting that Vertikal-1 does not seem to have been launched from Baikonur. Although the site has not been announced, it is described as being "in the territory of the European part of the USSR, at middle latitudes", perhaps in deference to the Soviet Union's Comecon partners. The rocket was assembled by a group from the USSR, East Germany, Poland, and Czechoslovakia, who were also present at the launch.

NUCLEAR ENERGY

Second Time Around

A SECOND Parliamentary bill to form two companies from the production establishments of the UK Atomic Energy Authority was published last week (*Atomic Energy Authority Bill*, HMSO, 4*s*). It is almost a carbon copy of the bill which was put forward by the Labour government last March but which failed to reach the statute book before Parliament was dissolved. The new bill proposes that nuclear fuel should be produced in the UK by British Nuclear Fuels Ltd, a company in which the government will always have a majority interest; a similar company, the Radiochemical Centre Ltd, will take over the AEA's booming, though more modest, commercial radioisotope business. It has also been suggested that private firms or individuals would eventually be encouraged to acquire a minority holding in both companies.

The Atomic Energy Authority has recognized for many years that its growing commercial activities would eventually have to be separated from its research and development functions. As a first step in that direction, a trading fund was set up in 1965 to finance the electricity generating facilities at Calder Hall and Chapelcross and the fuel production at the Springfields Works near Preston, where the formation of uranium hexafluoride from uranium ore has been improved since 1968 by the provision of a continuous fluidized bed process which cost £600,000. A large investment has also been made in production equipment for the coated pellet fuel to be used in future high temperature reactors and Springfields continues to produce the older Magnox fuel and the canned uranium oxide pellets used in advanced gas reactors. The trading fund also took over financial responsibility for the Radiochemical Centre at Amersham and it later assumed responsibility for the enrichment plant at Capenhurst, Cheshire, and the reprocessing works at Windscale, Cumberland.

The wheel has now come full circle and next April the two new companies will probably take over the facilities of the trading fund, which achieved a turnover of about £46 million last year. The companies can look forward to a world fuel market possibly worth £1,000 million a year by 1980, of which British Nuclear Fuels Ltd could expect about £200 million equally divided between home and overseas business.

As independent companies, they will be able to enter much more effectively into agreements such as those which led to the formation of the joint British–Italian fuel company Combustibili Nucleari and the collaboration with Gulf General Atomic in the US on water reactor fuels. The efforts also made along these lines by the Radiochemical Centre are highlighted by the foundation of Amersham-Searle, a radiopharmaceutical company formed in conjunction with the American company G. D. Searle. The fuel company will also be well placed to take advantage of the gas centrifuge pact agreed last March between the UK, Germany and Holland, parts of which have to be renegotiated early in 1971.

The Institution of Professional Civil Servants, which represents well over half of the 9,500 personnel involved in the change, was initially concerned at the possibility that the Conservative government would allow the fuel and radioisotope facilities to fall completely into private hands and therefore that people originally

employed by a public body would find themselves working for a private firm. The institution cautiously welcomes the bill as a whole but is continuing to negotiate with the government about some of its smaller provisions.

AIRBUSES

Veto Keeps Options Open

THE British government's decision to tighten the purse strings by refusing to inject a large sum of money into either the European Airbus or its rival, the BAC 3–11, makes the British civil aircraft market especially attractive to foreign salesmen. But the decision also gives the government considerable room to manoeuvre in its deliberations over the future of the Concorde project, and it will have wide-ranging implications for Rolls-Royce, whose future is by no means assured by the £42 million shot in the arm which it received recently from the government and the Bank of England.

Faced with a very difficult choice between the A–300B European Airbus and the BAC 3–11 (see *Nature*, **228**, 496; 1970), the government spent nearly two months deliberating before it turned its back on a large share in the business of manufacturing wide bodied civil aircraft. The BAC 3–11, on which the British Aircraft Company has already spent some £3 million, will die from lack of funds, and British European Airways, one of Europe's largest potential customers for the airbus, will have a choice between the Lockheed TriStar, the A–300B and the McDonnell Douglas Airbus.

Rolls-Royce will now be hoping that BEA will plump for the Lockheed TriStar and its RB 211–22 engines. Having lost the opportunity for selling a follow-up version of the RB 211–22 in the BAC 3–11, and with no share in the European Airbus or the McDonnell Douglas DC–10, Rolls-Royce will be looking for a long sales run with the TriStar to recoup some of the huge investment which the company and the taxpayer have sunk into the RB 211–22. BEA was known to be strongly in favour of the BAC 3–11, with the TriStar as its second choice, and it is therefore unlikely that the airline will take the DC–10. But, on the other hand, the A–300B involves substantial British participation from the Hawker Siddeley Aircraft Company, which decided to stay in the project when the British government pulled out in 1968. The airline is therefore being pulled both ways by British interests.

In making the decision not to support either airbus, the government was keeping one eye on the development of Concorde. The rapidly increasing costs of Concorde—now running at £825 million for the prototypes alone—will leave little money available for other civil aircraft, and a decision in favour of the BAC 3–11 would inevitably have made cancellation of the Concorde project more likely. Such a decision would, of course, be a singularly bad card to play while negotiations for Britain's entry into the Common Market are taking place. To help to quell such fears, however, Mr Frederick Corfield, Minister for Aviation Supply, told members of the House of Commons that he has been discussing with other governments more European participation in the manufacture of aero engines, and that he hopes such cooperation can be extended to the rest of the aviation industry.

MEGALITHS

Breton Origin for Tombs

from our Archaeology Correspondent

NEW radiocarbon determinations for megalithic tombs in Brittany substantiate the very early dating for these stone monuments and suggest that these tombs are the oldest in Europe. The unexpected possibility of a Breton origin for the custom of burial in megalithic tombs in Britain and even in the rest of north-western Europe must now be taken seriously.

The impressive megalithic collective tombs of western Europe have always seemed an astonishing achievement, somehow beyond the capabilities which could be ascribed to neolithic man. The very early carbon-14 dates produced by the French radiocarbon laboratories for the megalithic tombs of Brittany, setting them before any such tombs dated elsewhere, have been regarded suspiciously by prehistorians. For although the pros and cons of a West European rather than an East Mediterranean origin for the megaliths has long been argued, Iberia at the southern extent of their distribution and Denmark at the north have seemed the most likely regions for the development of megalithic architecture.

The very early dates in Brittany for what seemed the most sophisticated of these monuments, the corbelled passage graves, have also been doubted. The impressive burial chamber in these graves is reached by a long underground passage, and is roofed by a false vault of drystone construction. Examples of this building technique are seen in the tombs of Spain and Portugal, in Ireland (New Grange, Knowth) and in Scotland (Maes Howe) as well as in Brittany. A Breton example, Ile Carn, was dated in 1959 by the Groningen radiocarbon laboratory to 3280 BC, and other Breton megalithic tombs were dated by the French laboratories to about 3500–3000 BC. These determinations were too early for most archaeologists to accept. Unfortunately, one or two dates were more than a millennium higher—there is a determination of 6850 BC for a stone cist grave at St Michel. The necessity of explaining these as the consequence of the prehistoric use of bog oak did little to increase confidence.

Since 1959, however, further dates in the time range 3500 to 3000 BC have been accumulating, and radiocarbon determinations by Delibras, Guillier and Labeyrie (*Radiocarbon*, **12**, 421; 1970) give 3390 BC for the principal chamber at Ile Carn, and 3440 and 2890 BC for adjacent dolmens. These dates substantiate fully the previous early dates for Ile Carn and for other Breton tombs.

At present there are few carbon-14 dates for Iberia —conventionally the most favoured area for the origins of the European megaliths—and, in any case, the custom of collective burial in megalithic chambers may have developed independently in different parts of Europe. Yet, for the British Isles at least, these Breton dates may have considerable significance because the British neolithic farming economy was undoubtedly brought across the English Channel during the fourth millennium BC.

It has been considered that the unchambered long barrows found in England were a component of the first neolithic communities, with megalithic chamber tombs a later development. Recently, it has been

suggested that the timber mortuary house revealed by excavations in some British earthern long barrows (Ashbee, P., *Archaeologia*, **100**, 1; 1966; *Antiquity*, **43**, 43; 1969) may have been the prototype for the supposedly subsequent megalithic tombs of Britain (Daniel, G. E., *Antiquity*, **41**, 315; 1967). The early Breton dates now suggest a different conclusion, at which the earliest British megalith date—3160 BC for Monamore Cairn in the island of Arran (McKie, E., *Antiquity*, **38**, 52; 1964)—was just beginning to hint. It now seems possible that collective burial in megalithic chamber tombs was already a practice known to the first immigrant farmers, who reached Britain around 3500 BC. Indeed, any migrants who sailed from Breton shores after that time can scarcely have avoided a knowledge of megalithic architecture. It may be significant that the megalithic tombs of Britain lie chiefly in the west.

It remains to be seen whether a Breton origin for the British megaliths will find favour among archaeologists, at a time when migrationist explanations in prehistory seem to be going out of favour. Yet if the skills of the farmer were taken to Britain by immigrants, as undoubtedly they were, could not these first farmers have carried with them also the specialist skills of the megalithic undertaker?

TECHNOLOGICAL FORECASTING

Techniques under Fire

Paris, December

ARE the decision-making processes used in research and development an art—and a black art at that? The specialists at the Organization for Economic Cooperation and Development (OECD) are too reticent to give an explicit "yes" in reply, but at a meeting held in Paris during the last week of November they approved a report which is sharply critical of the well known decision-making techniques of which "think tanks" are at once the producers, stars and impresarios.

The report, which will be published in 1971, was prepared by Keith Pavitt (of the OECD Directorate of Scientific Affairs) and Claude Mestre (technical adviser to the French Transport Ministry). A direct outcome of an OECD conference in Paris in March 1969, the report is meant to familiarize government officials with the methods of analysis and rationalization of choice used in research and development. It bears out the suggestion that sophisticated operational research is not necessarily more productive than dead-reckoning empiricism. Born during the Second World War from defence needs, forecasting and decision-making techniques have not yet proved their effectiveness outside the area of military research, according to Pavitt and Mestre. To begin with, they explain that the arcane language of "rational" methods works against a meaningful exchange with politicians. Moreover, analysts often mix—unwittingly or not—political theory with technical hypothesis and they are always tempted in their forecasting to favour costs and advantages which can be backed up with statistics, while eliminating or underestimating elements that are sometimes very important but are not quantifiable or yet quantified. It is therefore to be feared that the fashion of highly refined technique "will lead, for purposes of prestige, to a search for very sophisticated methodology which conceals a serious ineptitude to analyse real situations".

After a general introductory statement, the authors review the principal decision-making methods which have been offered as miracle solutions to the never-ending problem of criteria of choice. Supporting its suggestions with concrete examples, the OECD report criticizes, among others, the Delphi technique (the panel of specialists used in this method are often badly selected; concern about obtaining convergent opinion tends to eliminate minority opinions and results in a triumph for conformism); simulation models (based all too often on insufficient data the applications of which are usually expensive and impractical); relevance trees ("despite their popularity, the validity of methods of this type is absolutely not proven"); the "scenarios" made famous by Herman Kahn (they are "costly and long to formulate without necessarily offering a guarantee for the proper anticipation of political, economic or social change and their influence on technological needs and trends"); the PERT method (a study of thirty-seven research and development projects in the United States showed that the use of PERT did not generate a single advance in technical performance); PPBS (planning, programming and budgeting system) on which, outside the military sector, we possess little positive or negative evidence.

On the face of things, although the authors sought to give a balanced view of the various methods now in vogue, the hundred page document is a fairly pessimistic report on the efforts of the past 20 years to create a solid foundation for technological forecasting and long range planning. In the realm of research and development, the new miracle men have yet to demonstrate their credibility.

BRITISH COUNCIL

Signs of Change

THE British Council, founded in 1934 to promote knowledge of Britain abroad and to develop closer cultural relations with foreign countries, emphasizes its dual role in the field of both science and the arts in its annual report for 1969–70. The recommendations of the Duncan Committee (*Report of the Review Committee on British Representation Overseas*, HMSO; 1969), that the council's functions in Europe should be expanded, are also given some prominence in the report. The council's proposed expenditure for 1970–71 amounts to about £14·6 million, of which about £13·5 million will be in the form of grants from the Foreign and Commonwealth Office (including contributions from the old Ministry of Overseas Development). Although this budget represents a standstill in real terms, it follows an absolute 5 per cent reduction in 1969–70.

The scientific activities of the council are concerned both with making British scientific work better known abroad and with encouraging collaboration between scientists in Britain and overseas. Visits and exchanges of personnel between British and foreign universities and research institutions are arranged or financed by the council and, during the past decade, the number of scientists involved in such activities has increased from 1,075 to 3,470. In addition, services to overseas students of all disciplines in this country are an important part of the council's work; 8,000 Commonwealth and foreign students were given assistance and advice when they arrived in Britain during 1969–70.

Future trends in the British Council have been hinted at in the Duncan Report which recognizes that the council "will become an increasingly important medium through which Britain will project her interests . . .", and it is also suggested that future reductions in expenditure would be very undesirable. The report specifically recommends that the British Council should concentrate its activities in Western Europe because of the importance of Europe in Britain's foreign policy. It also calls for more scientifically qualified British Council staff overseas. About sixty council personnel (8 per cent of the total) are scientists, and two-thirds of these serve abroad. A move to increase the proportion of scientists to about 20 per cent is suggested by the increase in scientific recruitment during 1970, which amounted to about one-third of the total.

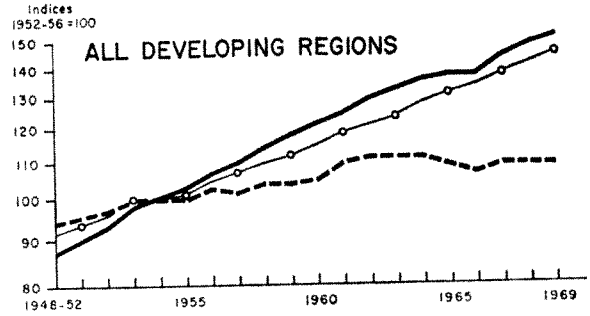
The possibility of increased council involvement in Europe would represent a distinct reversal of the policy, suggested by the Drogheda Committee in 1954, that British Council offices in Europe should be run down so that facilities could be concentrated in the developing parts of the world. From a scientific point of view, expansion in Europe would probably mean greater emphasis on the Council's libraries and information work. But if, as the Duncan Committee envisages, the council also retains its high degree of involvement with countries outside Europe, its grants in future years will have to rise considerably.

SALARIES

Another Pay Rise for Dons

ACADEMIC staff in British universities are to receive a 10 per cent increase in their salaries, backdated to October 1, 1970. The increase is the first to be negotiated under the new negotiating machinery for university salaries, and it is the second large increase secured by the AUT within twelve months. Although the award goes only half way towards meeting the claim put in by the AUT last August, it will help to redress the imbalance in university salary scales caused by recent large increases in the salaries of clinical staff in medical schools (see *Nature*, **226**, 786; 1970).

The AUT based its claim on similar criteria to those used by the Kindersley Committee for recommending increases in doctors' salaries. University pay scales were compared with those in the civil service and other professions, and the AUT also pointed out that a change in the staff/student ratio during the past few years has increased the work load on academic staff. These sums resulted in a claim for an increase of 20 per cent, which was discussed by a committee comprised of representatives of the AUT and university authorities. This committee eventually agreed to put forward a claim of 13 per cent to the government, and this was discussed in a second committee consisting of representatives of the first committee and of the government. The final result of the deliberations was an increase of 10 per cent.



Mr Laurie Sapper, general secretary of the AUT, is not at all despondent that the final award is only half the sum he asked for. "In view of the pressures on salaries in the public sector", he said, "we consider the settlement to be the most reasonable we could hope for." The AUT is also particularly pleased that the government has given an undertaking to review university salary structures during the present academic year.

UNITED NATIONS

Food for the Future

ALTHOUGH there may have been little improvement in the standard of nutrition available to the populations of needy and developing countries over the past twenty-five years, it has nevertheless been possible to support an unprecedented increase in world population during this period without major breakdowns in food supply. This is the most telling comment which emerges from the report *The State of Food and Agriculture 1970* (available from HMSO, 60*s*) published last week by the Food and Agriculture Organization of the United Nations (FAO). Indeed, it seems that the combined effects of long term planning at government level and the remarkable and recent advances in agricultural technology may have pushed many struggling countries past the critical point in their battle to achieve and maintain a sufficiently rapid rate of food production.

The year 1970 is of peculiar significance for the FAO for it is the 25th anniversary of the organization's foundation. Furthermore, as the title page of the report rather dramatically puts it, the world is on "the threshold of the second development decade". This has provided an excellent reason for the FAO to look back briefly over the progress which has been made since 1945, and to look forward, not too gloomily, to the problems which seem likely to threaten the future progress of world agriculture.

Growth of agricultural production (—) and population (o—o) in developing countries from 1950-1969

After the second world war, improved agricultural methods brought a transient increase in food production, but this was followed by a long period of disappointingly slow progress, during which production declined but populations increased unchecked. The nadir of this depressing period was the dismal harvests of 1965 and 1966, when only massive food relief averted disaster in many countries.

Progress since 1966 has been remarkable as a consequence of the increasing interest taken by the governments of developing countries in the methods available to increase their productivity, and in the new agricultural technology which has made this possible. Four topics are highlighted by the FAO report which may offer especial advantages or present outstanding challenges in the future. The first is the hope that the high-yield dwarf cereals, developed chiefly in Mexico, may continue to provide the bulk of the carbohydrate and protein required by the developing countries.

The second faces squarely the fact that meat protein is expensive and likely to become more so; the answer may lie in increased production of fish and vegetable protein, and in intensive breeding of pigs and poultry, which have a shorter reproductive cycle than ruminants. The last points embrace more political problems. Trade balances may have to be adjusted as countries which, in the past, have imported food now find they have a surplus to dispose of. And then there is the inevitable spectre of unemployment. Social problems engendered by the use of highly developed technology in developing countries are only now becoming widely appreciated, but clearly they merit further attention.

CHEMICAL INDUSTRY

Gloom at Albright

THE gloomy prediction by Sir Richard Powell, chairman of Albright and Wilson Ltd, that a loss during the second half of 1970 will probably wipe out the profit before tax of about £1·4 million earned in the first half is symptomatic of the ill wind blowing through the whole chemical industry. The company, which manufactures a variety of products ranging from detergent chemicals to pharmaceuticals, seems to be following the trend of the other chemical giants such as ICI and Laporte, which have also recently reported disappointing results.

Not all Albright's troubles, however, can be traced back to the inclement economic atmosphere. The £20 million phosphorus plant built by the Electric Reduction Company of Canada Ltd (the ERCO division) at Long Harbour, Newfoundland, has been a source of trouble since it first started operating about two years ago. The plant was closed for several months during 1969 because of evidence of water pollution, and about £1 million was spent on measures to prevent the discharge of phosphorus into the sea. The first full shipment of elemental phosphorus by specially designed bulk tanker did not reach Britain until December 1969, although the plant was operating again in July.

It has now been announced that one of the two furnaces at Long Harbour has been shut down again because of breakage of the carbon electrodes used in the electrothermal extraction of phosphorus from the phosphate rock ore. Other modifications have also become necessary and it would seem that the target annual output of 70,000 tons is still a long way off. Although the company produces elemental phosphorus elsewhere in Canada and in Australia, the Long Harbour setback has forced it to buy phosphorus from other producers and to recommission old plant in the UK. Fortunately, many of the detergent chemicals are produced from the ore by a wet process.

Depressed markets, late delivery of equipment and shortages of sulphuric acid are responsible for troubles in the Marchon division of the company, which produces large quantities of cement and comprises several European firms, and in the Canadian associated company Belledune Fertilizers Ltd which is running at a considerable loss, principally because of the poor state of the fertilizer market. Even the Midland Silicones division, which manufactures greases, rubbers and electrical insulating material and has been a healthy member of the group in the past, has been obliged to announce harsh measures to combat rising costs and the other consequences of inflation.

Parliament in Britain

Third London Airport

THE Roskill Commission on the Third London Airport hopes to submit its report to Parliament by the end of December. Announcing this in reply to a question from Mr William Benyon, Mr John Davies, Secretary of State for Trade and Industry, also said that sufficient time will be allowed for a full debate on the recommendations of the commission, but the government feels that it must act promptly in deciding on the siting of the airport. The Roskill Commission is considering possible sites at Cublington, Foulness, Nuthampstead and Thurleigh. (Oral answer, November 30.)

Abortions

MR MICHAEL ALISON, Under Secretary of State at the Department of Health and Social Security, said in reply to a question from Mr Selwyn Gummer that 84,764 abortions took place in National Health Service hospitals between the time when the Abortion Act came into effect in November 1968 and October 28, 1970. He also said that the effect of the Act on the availability of hospital facilities varies from region to region, but no information on the amount of time spent by surgeons on terminations of pregnancy is available. Asked whether there is need for an investigation into the workings of the Abortion Act, Mr Alison said that the Secretary of State for Health and Social Security hopes soon to make a statement. (Oral answers, December 1.)

River Pollution

A SURVEY of the state of the rivers of England and Wales, being undertaken by the Department of the Environment and the Welsh Office, should be completed late next year. Mr Peter Thomas, Secretary of State for Wales, said that the report of the survey will provide an assessment of the cost of restoring polluted rivers to a satisfactory condition and of maintaining them in that condition. (Written answers, November 30.)

Bronchial Disease

IN reply to a question from Mr John Biggs-Davison, Mr Michael Alison gave the official figures for the yearly death rate in England and Wales from bronchial diseases. The figures are as follows:

Year	Asthma, emphysema, bronchitis, bronchiectasis	Malignant neoplasm of trachea, bronchus and lung
1965	692	554
1966	734	563
1967	637	585
1968	751	593
1969	772	610

Research Association

MR JOHN DAVIES, Secretary of State for Trade and Industry, said that he is reviewing the policy concerning grants to research associations for which his department retains vote responsibility. In the meantime, the department of Trade and Industry is continuing to reduce grants progressively so that industry bears an increasing proportion of the costs of the associations. (Written answer, November 30.)

NEW WORLD

Seaborg Brings Strife to AAAS

by our Washington Correspondent

A DEBATE that has long been simmering within the American Association for the Advancement of Science has been brought to a head by the election of a new president. With many of the returns from this year's postal ballot already in, Dr Glenn T. Seaborg, chairman of the Atomic Energy Commission, seems certain to be the winner. But the board of directors of the AAAS is divided both as to the terms on which Seaborg was asked to stand as president and because his tenure of an important government office is likely to inhibit the new responsiveness to social issues that some members would like the association to develop.

Issues of personality apart, the basic argument over Dr Seaborg's candidacy is on the one hand between those who believe the AAAS must preserve its scientific chastity and not fritter away its reputation by becoming a platform for the political views of particular groups, and on the other between those who wish the association to become more active as the representative of scientists on the numerous social issues that have a scientific background.

The board of directors of the AAAS voted in March this year to seek a ten-fold increase in the membership of the AAAS (the present membership is 130,000) and to become much more deeply involved in issues of social relevance. The activists in the AAAS have no personal criticism to make of Seaborg but fear his presidency would impede these plans in several important aspects.

Chief among them is that as chairman of the Atomic Energy Commission Dr Seaborg would face a conflict of interest in many of the issues with which the AAAS is involved. Senator Edmund S. Muskie, for example, has asked the AAAS to adjudicate the charges against the Atomic Energy Commission's policy on radiation safety that have been raised by two of its employees, John W. Gofman and Arthur R. Tamplin of the Lawrence Radiation Laboratory. Nor would Dr Seaborg, it is feared, find it easy to countenance studies that could turn up critical verdicts on government policy; a prime example is the study of the effects of herbicides in Vietnam recently commissioned by the AAAS—its most independent step so far and one that was taken after a difficult internal debate.

Activists in the AAAS and on its board of directors are also anxious to see the association's presidents and chairmen (after a year in office the retiring president assumes the rather more important job of chairman of the board of directors) devote more time to their offices than has been customary in the past, and more perhaps than Seaborg, with his many duties, may be able to give.

Another issue that has been raised is that Seaborg is president of Science Service Inc, publisher of the popular magazine *Science News*, which because of financial troubles was until recently seeking a merger with the AAAS. At a meeting in October this year the board of the AAAS decided against the merger but at the time Seaborg's candidacy was proposed in June there was the possibility that he would be placed in the position of heading both parties to the merger.

These misgivings are strongly denied by Dr Athelstan Spilhaus, present president of the AAAS and the original advocate of Seaborg's candidacy. On the issue of the time needed for the job Spilhaus said last week that having seen Seaborg operate as chairman of *Science Service* (of which Spilhaus also is a trustee) he knew that Seaborg was a man who "gives as much time as the job requires". Although the job of president takes up a great deal of time it can be fitted in at weekends and so forth. Of the possibility of a conflict of interest, Spilhaus says that Seaborg would of course dissociate himself from any matter concerning the AEC. As for other matters with a political content the AAAS has in the past had holders of important government offices serving as president—one former president, Dr Alan T. Waterman, was also director of the National Science Foundation. Dr Spilhaus added that during his term as president he has in any case been opposed to the AAAS getting involved in what he calls "pseudo-political science"—"Many of the people urging the herbicide study were using the AAAS as a podium to present their own views on the Vietnam war."

Another matter on which Spilhaus and his board of directors seem to have differed is the question of whether Seaborg's candidacy for president of the AAAS should have been made conditional on his being no longer chairman of the AEC. Candidates for president are chosen by the seven member Nominations and Elections Committee of the AAAS, of which Spilhaus is chairman. When the committee met in June to decide on candidates for the present elections, it seemed probable that Seaborg, whose term as chairman of the AEC had then expired, would not be reappointed. In fact Seaborg announced he had accepted a further term of 6 years shortly after being invited to stand as candidate for the AAAS presidency. Did the Nominations and Elections Committee believe that Seaborg would not be serving again as chairman of the AEC, and was this made a condition of his being asked to stand as president of the AAAS? The committee does not keep minutes of its meetings, but of the members who could be reached this week three, including Spilhaus, are certain that no conditions were placed on Seaborg's candidacy and one member, at least, believes that Seaborg's chairmanship of the AEC was not discussed at all, personal merit only being considered.

The board of directors was not informed by Spilhaus of the nominations (nor is it bound to be) until September and learnt with some disquiet both that Seaborg was a candidate and that he had agreed to stand. At a meeting held after an executive session of the board in October, several members decided unanimously to ask the board's chairman, Dr H. Bentley Glass, to invite Seaborg to reconsider his acceptance of the candidacy. Both Glass and Spilhaus and at least one other member of the board were absent from this meeting, which is not regarded by Spilhaus and the Executive Director of the AAAS, Mr William Bevan, as an official meeting of the board. Glass met with Seaborg but it seems did

not tell him that the board of the AAAS wished him to withdraw. Seaborg nevertheless called Spilhaus, apparently saying he was thinking of withdrawing his candidacy. Spilhaus said last week he urged Seaborg to stand because "I have great respect for him—he is a fine scientist, has a fine administrative ability, and I think he would make a fine president". Spilhaus explained that as chairman of the Nominations Committee, he felt it his duty to prevent the board interfering in nominations, otherwise it could perpetuate itself. As it happens the other candidate for presidency, Richard H. Bolt, chairman of the Massachusetts firm of Bolt, Beranek and Newman, is also a member of the AAAS board.

Whether or not the drawbacks of Dr Seaborg's candidacy are more real than imagined, the affair has already caused trouble on the staff of *Science*, the weekly journal published by the AAAS. The editor of *Science*, Dr Philip H. Abelson, declined to publish an article about Seaborg's candidacy written by a staff member, Philip M. Boffey, at the suggestion of Daniel S. Greenberg, the able and widely respected news editor of *Science*. As a result of Abelson's refusal Greenberg has resigned with effect from December 18.

The chief functions of the AAAS hitherto have been its publication of *Science* and its annual convention. There is a feeling in some quarters that with *Science* increasingly under challenge from young people and in congress, the AAAS should adopt a more positive role. Although precluded by its constitution from undertaking political lobbying, the association is well poised to become a more independent voice of the scientific community than, for example, the National Academy of Sciences can be. Unlike its counterpart, the British Association for the Advancement of Science, the AAAS is prestigious, well organized and financially stable. In the past, its board of directors has been divided and afflicted with what one observer calls "Prima Donnaism", but there now seems at least a measure of consensus that the association should be less timid in tackling social and political problems on which scientific knowledge can be brought to bear, even if the proper degree of involvement has yet to be worked out. Whatever difficulties Seaborg may face by virtue of his public office in coping with this issue, nobody doubts he is otherwise admirably qualified for the job of president of the AAAS.

OBSERVATORIES

Tucson Must Shed Less Light

by our Astronomy Correspondent

Tucson (Arizona), November

THIS city in southern Arizona has become the closest thing to Mecca for American astronomers, with four observatories within fifty miles—five if the microwave installation of the National Radio Astronomy Observatory on Kitt Peak is counted separately. Already there are six reflectors of between 16 and 84 inches on the mountain, run by the Association of Universities for Research in Astronomy (AURA). A 150-inch reflector is well on the way to completion and the blank for the corresponding instrument in Chile stands in the yard of the well-equipped AURA base in the city of Tucson to follow the Kitt Peak mirror on the figuring machines there. The Steward Observatory of the University of Arizona has a 36-inch and a 90-inch reflector on the mountain, and a 21-inch reflector on the campus in Tucson, and the university's lunar and planetary laboratory has five reflectors between 21 and 61 inches in the Catalina mountains. To the south, the Smithsonian Astrophysical Observatory has a 60-inch reflector on Mount Hopkins, together with smaller instruments for satellite ranging, and the 10-metre light bucket for gamma ray work.

Tucson as photographed at night from Kitt Peak, 1965.

Unfortunately for astronomy, however, the city of Tucson is growing as rapidly as the telescopes multiply, and the observatories in what once seemed to be an ideally remote area are becoming bothered by city lights. Now the directors of the observatories concerned—B. J. Bok of Steward Observatory, D. S. Heeschen of NRAO, G. P. Kuiper of the Lunar and Planetary Laboratory, N. U. Mayall of Kitt Peak National Observatory, and F. L. Whipple of the Smithsonian—have put their names to a pamphlet setting out the situation and the remedy. With the somewhat catchpenny title *Light Pollution: A Threat to Astronomy in Pima and Santa Cruz Counties, Arizona*, their paper includes what astronomers would almost regard as atrocity photographs showing the alarming view of Los Angeles from Mount Wilson as an example of the worst that could happen. The prognosis for the observatories around Tucson is luckily a little better. The people of Tucson are proud of the astronomy that goes on in their neighbourhood, and are expected to cooperate in the simple measures to keep the southern Arizona skies dark at night. What the astronomers would like to see are shields fitted to street lights to prevent light from escaping above the horizontal, roads to have a black surface (which would exclude the use of concrete), and filters fitted to lamps to cut out the violet and ultraviolet components which contribute little to the illumination but interfere with astronomical work. In particular it would be good to do away with the violet and ultraviolet emission lines of mercury vapour lamps. If anything, the pamphlet says, suitable filtered mercury lamps leaving only the green and yellow lines would be preferable to other sources of illumination which cause greater interference.

To this end the pamphlet proposes that Tucson should adopt an ordinance making the shielding and filtration of outdoor lamps mandatory. So far the only obstacles seem to be the availability of suitable

filtered lamps—the market in the Tucson area may not be large enough for manufacturers to provide what is needed—and possible objections from purveyors of food who may be afraid that the filtered light will make their wares appear unwholesome. But with Tucsonians appreciating the worth of the facilities in their area, the outlook looks favourable.

ENVIRONMENT

Senate Shoots Down SST

by our Washington Correspondent

BOTH the friends and foes of the supersonic transport were amazed by the vote last week by which the Senate resolved to cut off the funds for continuing with the aircraft. Up until the morning of the debate the $290 million appropriation for the construction of two prototypes of the Boeing Company seemed assured of a certain, if narrow, passage. Even Senator William Proxmire, the sponsor of the amendment to strike out the funds for the SST, had expected at best to get within a few votes of a draw.

Last year the Senate voted to continue with the SST by a margin of 58 votes to 22; this time the tide flowed against the aircraft by a decisive 52–41 vote. What made so many Senators change their minds? The threat of losing markets to foreign competitors, in this case the Anglo-French Concorde, is usually a persuasive argument in Congress, added to which the SST has the support of the two powerful Senators from Washington state, where the Boeing Company has its headquarters—Henry Jackson and Warren G. Magnuson, chairmen of two key committees (Interior and Commerce) and wielders of considerable power and patronage. Of the two chief arguments against the SST raised by the environmentalists, the question of climatological disaster is ominous but visibly far from proven, and the issue of the sonic boom was cunningly defused the day before the crucial debate by Senator Magnuson, who rushed through the Senate a bill prohibiting overland flights by the SST and requiring that its engine noise be no louder than that of subsonic jets in present use.

There seems little doubt that the environmental issue was decisive in swinging the vote against the SST despite all the odds in the project's favour. Although the specific arguments advanced by the environmental pressure groups may have been resistible individually, their intensive lobbying and activities in Senators' home states were not to be lightly dismissed; after the mid-term elections last month no Congressman wishes to get tagged with an anti-environment label if he can help it. As Senators on both sides of the debate pointed out, the movement against the SST draws much of its strength from wider issues, of which the plane itself was only a symbol. These are that technology must be controlled and that glamour projects such as the SST should have a lower priority than the tackling of domestic disorders. Certainly the Senate's vote will be interpreted in this sense, and will remain a decisive influence on future projects of this nature, even if the funds for the SST should be reinserted at the forthcoming conference between House and Senate. The House of Representatives voted in favour of the aircraft and as it happens the seven conferees appointed by the Senate include Senator Magnuson, and three other supporters of the SST. The Senate is unlikely to accept any conference agreement that writes back the full appropriation for the SST but a smaller sum that would still allow development to proceed could well pass.

The Senate vote on the SST cut across party lines—the 52 members who voted to delete the funds included 34 Democrats and 18 Republicans. Most of the Senate establishment, however, supported the project, twelve of the sixteen chairmen of standing committees voting in favour. The debate was notable for an unusually conspicuous piece of *force majeure*. Senator Mark Hatfield of Oregon found an item in the Transportation bill (of which the SST appropriations are a part) forbidding the extension of an airport in Oregon until further environmental studies had been undertaken. Claiming that exhaustive studies had already been made the Senator begged Senator Magnuson, the manager of the bill, to strike this clause out. Magnuson, chairman of the Commerce committee which prepared the bill, only replied "Let me say to my colleagues from Oregon that we will take this matter up after action on the Proxmire amendment (to strike out funds for the SST)". When Hatfield's name was called on the roll call he failed to vote and it was explained that he had had to catch a plane to fulfil a speaking engagement of long standing. Immediately after the SST vote Magnuson allowed the restriction on the Oregon airport to be lifted. Hatfield's vote, it turned out, was not needed; and in fact Senator Magnuson, according to one of his aides, released four votes pledged to him when he saw that the SST could not win anyway.

COMMUNICATIONS

Demise of Scientific Journals

by our Washington Correspondent

"ANOTHER damn, thick, square book—always scribble, scribble, scribble, eh, Mr Gibbon," the Duke of Gloucester is said to have observed on being presented with a new volume of the history. Not grumbling but apoplexy would be the reaction of Gibbon's patron to the literary output of today's scientific community. The average life scientist produces not one book every two decades but more than four publications a year, two of them being full length research articles. Added to which, many scientists are "notoriously poor writers", according to a report put out last week by the National Academy of Scientists.

The activities of this scribbling multitude have come under the scrutiny of the committee under Dr Philip Handler, president of the National Academy of Sciences, and are the subject of a special chapter in the report on the life sciences issued last week (see *Nature*, **228**, 902; 1970). Discussing journals as a medium of scientific communication, the committee predicts that journals will eventually be rendered obsolete by the computer console, although it may take ten years before each major research centre in the United States possesses a suitable terminal, a further decade for small groups of scientists to come to own consoles and yet another ten years to provide links with other continents.

The daunting volume of the input into the system is documented by a questionnaire sent out to biological research workers in 1967, from which it appears that each scientist contributes on average four distinct publications to the "literature" annually (see Table 1). Surprisingly, the committee reports that although few

scientists can read everything of potential interest, most consider they remain reasonably *au courant* with events on the forefront of their own disciplines. They keep up, however, not just by private reading, but by attending meetings and exchanging publications under the aegis of "invisible colleges". Some 90 per cent of life scientists polled in the survey had attended at least one meeting in 1966, 15 per cent had attended four or more, and nearly 10 per cent managed to participate in meetings outside the United States. Holders of purse strings should remain sympathetic to requests for travel grants, the committee argues.

Table 1. PUBLICATIONS REPORTED IN 1966 BY 12,364 LIFE SCIENTISTS.

Type of publication	Investigators reporting one or more	Number published	Average* no. per respondent
TOTAL, ALL TYPES	10,727	50,858	4·1
Full-length research articles	8,801	24,573	2·0
In-house publications	2,527	7,684	0·6
Books and monographs	442	489	<0·1
Chapters in books	1,710	2,416	0·2
Major reviews	887	1,134	0·1
Abstracts of original research	4,668	9,674	0·8
Other publications	2,028	4,888	0·4

*Average numbers based on 12,364 respondents to individual questionnaire.

Among the 13,000 biological journals now churning forth from the presses the academy committee finds it possible to identify—by an unstated method—about 1,000 journals in which more than 90 per cent of the truly significant work in biology appears. *Biological Abstracts* covered some 7,400 journals in 1968 but most of these are unlikely to publish anything that will materially advance the progress of science. Despite this acrid but probably accurate judgment, the committee urges federal government support for journals, some of which are being hit by rising costs and are on the way to pricing themselves out of business.

MIT

Paved with Good Intentions

by our Cambridge Correspondent

THE Commission on MIT Education has just issued a major report called "Creative Renewal in a Time of Crisis" which attempts to take stock of the role of MIT in the educational world today. There is perhaps no university anywhere that so confidently regards itself as closely associated with national goals, the quality of a technological society and the responsibility for mapping out the future of this society. However, because it takes itself so seriously, this effort at re-evaluation comes in a uniformly dull format. Too many witnesses, too many words, too many platitudes and too many authors, one is forced to admit.

The committee of 12 had submissions from about 350 witnesses. Most of these are at present associated with MIT. No one from Caltech gave evidence, and only three from Harvard, 5 minutes' bus ride away. The witnesses from all other universities numbered about 20. In view of the importance which MIT correctly attaches to itself, one would have thought that a balanced national view was every bit as important as testimony from the insiders. The report reads very much as a lowest common denominator inflated with some truly ghastly expressions of good intentions as "Such fundamental questions as the nature of truth and explanation, the sources and validity of human values, the qualitative distinctions between styles and aesthetic judgements, the role of reason and passion in individual social behaviour, ought to form the core of much of undergraduate education". Well, everyone would agree with that, all 350 of them, but such statements provide no concrete help in achieving creative renewal.

If one carps at the style of the report, it is mainly because the voluminous prose seems to cover up a genuine inability to answer very specific questions. MIT has as many graduates as undergraduates—would it make sense to become a totally graduate school? Is it likely that in ten years the physical sciences will have experienced such a severe recession that MIT ought to be looking for new fields? If the environment and urban problems are here to stay, what in MIT is peculiarly suited to solve these problems, and how are students to be attracted? How does Defense Department spending fit into MIT's future? Why are so many MIT students both outstandingly brilliant and also depressed by the place? Is it possible to convey that overall view of science which its best practitioners have at their fingertips without the drudgery of learning much by rote? The report admits that it is only dealing with general issues, and eschews practical details, but many will question whether the general issues discussed fully cover the problems facing MIT.

The chief recommendation of the report is for a new look at undergraduate education. This is sound, as undergraduate education is always worth a new look. MIT has recently been quite extensively involved in experiments to make its teaching "more meaningful". The new proposals would broaden the first two years by the creation of what is called a "First Division" in which the responsibility for education would fall on more shoulders than it does at present and an attempt would be made to give students an overview of science. Perhaps the most interesting proposal is that an experiment should be made involving the teaching of students from the age of 16. This is certainly worth serious attention in the case of students who know at that age that they are committed to a scientific career. The report pays the customary lip service to the humanities.

On graduate education, the only proposals which appear to have major significance are that more attention should be paid to training for teaching and (probably related) that credit be given in the form of a degree for those students who are unable or unwilling to pursue research but who can perform a "consolidation of knowledge" or a "scholarly review".

What future, then, for MIT education? The two commission members unhappy with the report voice concern over its inadequacy, its lack of depth and its preoccupation with minimal adjustments. They throw into the arena some more debatable topics, and because the commission has a year to run it is to be hoped that more concrete discussion will follow, if not of the generalities of the report, at least of the minority views. Ultimately, however, committees are not as effective as people at changing things. If sufficient faculty members at MIT set personal examples of high quality teaching such reports as this will prove unnecessary.

NEWS AND VIEWS

Viruses and Burkitt's Lymphoma

AMIDST the flurry of activity which currently surrounds the enzymes which synthesize DNA from RNA of RNA tumour viruses and leukaemia cells, it is as well to remember that most cancers in man and animals do not have the properties of infectious diseases. Further, the only known viruses which seem to be intimately associated with human cancers are the herpes viruses, with DNA genomes, and in particular Epstein Barr virus (EB virus) which may be causally related to Burkitt's lymphoma, a common cancer of East African children, and nasopharyngeal carcinoma, a common cancer of certain oriental populations.

It is almost ten years since Burkitt first suggested that the restricted geographical distribution of Burkitt's lymphoma and its apparent dependence on climatic factors could be accounted for if this tumour were caused by a virus disease transmitted by some insects. And since 1964, when Epstein and his colleagues detected a herpes virus, EB virus, in a line of Burkitt lymphoma cells in culture, a great deal of conflicting evidence about the significance of this virus in the aetiology of the lymphoma has accumulated. The case for asserting that any human cancer is caused by a virus must rest on a body of circumstantial evidence rather than a single piece of direct evidence. But what would constitute an overwhelming case? What circumstantial evidence is crucial? Ideally, it must be shown that infection precedes the development of the cancer and that the tumour cells contain molecules specified by the virus. Added to this, demonstrations that the virus, or viruses of the same group, can transform cells in culture, that the virus can induce tumours in animals, that vaccination against the virus reduces the incidence of the cancer, and finally that the epidemiology of the cancer is that which is expected for an infectious disease, should add up to an indisputable case.

These criteria are obviously extremely difficult to establish for any human virus, and the herpes viruses in particular have two characteristics which further compound the difficulties. First, the herpes viruses are ubiquitous and, second, they tend to persist in an infected person for their lifetime. Given these added obstacles, how strong is the case for linking EB virus with Burkitt's lymphoma or nasopharyngeal cancer? The epidemiology of the disease and of EB infections indicates that mere infection with EB virus is not sufficient to cause the cancers. If the virus has an aetiological role it must be in combination with some other environmental factor because in most regions of the world infection with EB virus either goes unnoticed or results in glandular fever but not lymphoma or carcinoma. The nature of the putative second factor is unknown, although Burkitt has suggested that for East African populations with a high incidence of Burkitt's lymphoma the second factor might be malarial infections. Attempts to vaccinate a population in a high risk area have not yet been made so there is no evidence on that score. EB virus seems to change the growth properties of lymphocytes in culture; it may therefore be capable of transformation but whether it can cause tumours in animals remains to be seen.

What evidence, then, is there to suggest that tumour cells from Burkitt's lymphoma or nasopharyngeal carcinomas contain EB virus nucleic acids, or antigens which are specific for EB virus? On pages 1053 and 1056 of this issue of *Nature* three of the leading groups, which have for several years been pursuing this problem, report the results of collaborative investigations which strengthen the argument that there is an intimate association between the genomes of EB virus and Burkitt lymphoma cells and nasopharyngeal carcinoma cells. In the first of the two articles Gunvén and Klein, the Henles and Clifford report that serological tests on ninety-six patients with Burkitt's lymphoma have revealed antibodies directed against the EB virus capsid antigen, and a virus-determined antigen which appears on the surface of infected cells. Relatives and near neighbours of these patients and fifty-three patients with tonsillitis were selected as controls and their sera contain significantly less of these antibodies. As with earlier, comparable investigations, these results indicate that patients with Burkitt's lymphoma are subject to continued antigenic stimulation from EB virus antigens.

In the second report, the same workers, together with Zur Hausen, Schulte-Holthausen and Santesson, describe the detection, by hybridization experiments, of EB virus DNA in biopsy material taken from patients with the lymphoma or carcinoma. Using the DNA to DNA hybridization technique which Zur Hausen and Schulte-Holthausen developed for detecting EB virus DNA in a line of cells derived from Burkitt tumour material but which does not yield virus (*Nature*, **227**, 245; 1970), Zur Hausen and his collaborators apparently find from one to twenty-six genome equivalents of EB virus DNA in the cancer cells of the various patients they have studied. Of course, trying to detect a small amount of viral DNA mixed with an excess of cellular DNA is fraught with technical difficulties and pushes the hybridization method to the limits of its resolution; it is therefore crucial to prove that the hybridization which is being measured is truly specific for the viral DNA. Zur Hausen and his colleagues claim that the hybridization they are measuring is specific because none could be detected between EB

virus DNA and the DNA of cells infected with a related herpes virus, cytomegalovirus, or the DNA of chick cells from Marek's disease tumours, which are caused by a herpes virus. Further, the DNA of herpes simplex virus did not hybridize with Burkitt's lymphoma or nasopharyngeal carcinoma biopsy material.

Although there was no clear correlation between the number of genome equivalents of EB virus DNA in particular biopsy specimens and the concentration of antibodies against the viral capsid antigen and the virus-determined surface antigen, the presence of at east some viral DNA correlates with the generally high concentrations of these antibodies. It seems, therefore, that as well as viral antigens the cells of Burkitt's lymphoma and nasopharyngeal carcinoma also contain EB virus DNA. But does this simply mean that these cancers become secondarily infected with a persistent, but latent, EB virus ? That remains the central and unanswered question although Zur Hausen *et al.* believe the finding that in any one patient the number of genome equivalents of EB virus DNA is constant when biopsy material is taken from a tumour at different times argues for more than an extension of a casual but persistent EB virus infection. Sceptics, however, may be less willing to persuade themselves on the strength of that evidence.

Forecasting Turbulence in the Air

CLEAR air turbulence has become a speciality of the Royal Radar Establishment, Malvern, where the high power radars which are needed to obtain reflexions from the refractive index inhomogeneities are available. Earlier this year the Meteorological Research Unit at Malvern published photographs from the radar screen showing the evolution of a patch of turbulence, the first time that the evolution has been followed from a single patch rather than by the less satisfactory expedient of piecing together observations at different times (*Nature*, **227**, 260; 1970). To round off that paper the Malvern team have now proved that the curious braided structure seen on the radar screen truly represents the turbulence that is felt by aircraft (see page 1065).

The first thing to be said, however, is that there is not a great deal that can be done about clear air turbulence apart from some fairly rudimentary predictions. To begin with, clear air turbulence is invidious because it occurs where there is no hint of trouble —in an optically clear atmosphere. In physical terms the turbulence is a form of Kelvin–Helmholtz instability which arises in the interfacial zone between two moving fluids, and can occur throughout the troposphere and into the lower stratosphere. Two favoured locations are the upper and lower boundaries of jet streams, and it is the turbulence associated with the jet stream within the westerlies flowing over England that is the object of the Malvern studies in this paper. When the radar echoes are converted into a cross-section view of the atmosphere the turbulence looks as much as anything like the breaking of waves—the braided echoes reported in the earlier paper—and this is a not over-simplistic view of the evolution of a Kelvin–Helmholtz instability in the atmosphere.

What Browning, Watkins and Starr of the Meteorological Research Unit, and McPherson of the Royal Aircraft Establishment, are reporting this week are the data from an instrumented Canberra aircraft which was in the air while the radar was recording echoes from clear air turbulence. Turbulence was recorded by the accelerometer on the aircraft when the flight path was near patches of turbulence as recognized by the radar, and comparisons between the wavelength and amplitude of the turbulence as measured by the aircraft and the radar are as close as might be expected. The radar detected all the turbulence experienced by the aircraft along the flight path which coincided with the altitude of the strongest turbulence, but there was some light turbulence at a lower altitude which went unrecorded by the radar.

It would be nice if the Malvern work meant that one day soon aircraft could be fitted with radar to detect clear air turbulence. The 10·7 cm radar transmitter operated by the Meteorological Research Unit has a peak power of the order of 1 MW and is fed into a 25 m diameter dish aerial, however, and even then is limited to a horizontal range of about 50 km and heights up to about 12 km. The alternative approach, prediction of clear air turbulence, is not well developed but it is in this direction that the studies going on at Malvern will be useful. The paper by Browning and Watkins earlier this year made a start by setting a seal on the way the evolution of clear air turbulence has been inferred from many separate observations, chiefly by the Americans. The way ahead is to find out more about the factors that control the appearance or non-appearance of the turbulence, and obviously a ground-based radar able to scan the atmosphere at frequent intervals is going to be more useful than an instrumented aircraft.

But one serious problem at present is that there can be doubt about the strength of the turbulence from the radar observations alone. Echoes from patches of light turbulence are often to all intents and purposes indistinguishable from echoes from strong turbulence, and up to now the resolution of the ambiguity has had to come from radiosonde or aircraft measurements of the strength of the wind shear. To deal with this problem from the ground the Malvern group, and others, are developing Doppler radar methods which will give direct information about the turbulent velocities. This will be the next advance on the observational side of clear air turbulence.

LIQUID THEORY

Random Configurations

from our Molecular Physics Correspondent

IF there is an orthodoxy in the theory of liquids—and recent conference proceedings suggest that there is—it has little place for notions which depart very far from the familiar, well founded and, regrettably, somewhat sterile formalism of Gibbsian statistical mechanics.

The Bernal "random geometric" approach to liquids, which is the subject of two new articles by J. L. Finney (*Proc. Roy. Soc.*, A, **319**, 479, 495; 1970), is highly unorthodox. It cuts across most of the niceties of conventional many-body theory, appealing to crystallographic rather than mechanical insight and seeking to capture the essence of the liquid in the statistical properties of nearest-neighbour configurations reduced to units of the polyhedron. Although intuitively satisfying, this primarily visual approach proves to be of some mathematical sophistication, so much so that, to the dismay of the formalists, the theory cannot be placed in any recognizable chapter of geometry, far less reduced to a single set of equations. In fact, no method has been described within the theory to relate the polyhedron statistics either to the fundamental energy surfaces in configuration space or to the practical calculation of thermodynamic entropy. Thus, not surprisingly, its advocates have so far set greater store by its descriptive than its predictive powers, being chiefly concerned to check their statistics against measurements on mechanical or computer simulated random models. But if the Bernal theory lacks the formal virtues of conventional statistical mechanics, its informal ones are none the less compelling. The original articles (*Nature*, **183**, 141; 1959: **185**, 68; 1960) can hardly be read without the conviction that the author is at least talking about liquids as we know them —". . . homogeneous, coherent, essentially irregular . . ." and abounding in entropy—rather than about some discouraging cypher of configuration integrals.

In Finney's work, realistic computer-simulated liquids similar to those which appear in recent "Monte Carlo" thermodynamic studies are compared for the first time with the random sphere packings originally constructed by Bernal. A detailed analysis of the statistical distribution of configurational polyhedra confirms that Bernal's primitive ballbearing and ball-and-spoke models gave an essentially correct picture of the instantaneous geometry of a monatomic liquid, in which the principal structure-determining factor now seems certain to be the hard, repulsive potential rather than the soft attractive part. Finney also compares his results for liquids with those for simulated solids at their melting point and he demonstrates clearly the discontinuity in the polyhedron statistics at the melting point.

Unfortunately, important as these results are, they bring us little closer to a solution of the two central problems: what is the precise relationship between the statistical geometry and the configurational energy function for N atoms, and what are the essential determinants of the statistical geometry and how are they connected with the definition of thermodynamic entropy? It is not difficult to accept that the instantaneous geometry of a large enough sample of liquid contains all the information about its wanderings in phase-space sufficient for an accurate calculation of its entropy. It is a plausible next step to maintain that this information resides in the statistics of polyhedral types related to nearest-neighbour arrangements. Beyond this, the trail disappears into the sand. Finney makes the tentative suggestion that the key to an algorithm for computing configurational entropy may lie somewhere in homology theory.

What is certain, however, is that there is little chance of an easy synthesis of Bernalian and Gibbsian statistical mechanics for, by insisting on the polyhedron as the descriptive unit, the geometrical theory seems to begin at the level of four and five-body angular correlations—several stages beyond the most refined predictinos of ordinary statistical mechanics. This is both its strength and its weakness; it justifies itself as a truly structural theory of liquids, which can hardly be said of the conventional theories, but only at the risk of being over-determined and neglecting what plausible simplifications there are. For example, it seems to waste altogether the two-body force assumption, one of the few reasonable approximations which enter nicely into the ordinary theory.

Nevertheless, as Finney is careful to point out, the search for a formal relationship between statistical geometry and entropy is worth pursuing for reasons which go beyond the microscopic theory of liquids. There are many other disordered systems in nature and technology—powders, fluidized beds, biological aggregates—whose properties might well be elucidated through a deeper and imaginative understanding of what might be called the geometry of chaos.

QUANTUM ELECTRODYNAMICS

Gravity's Role in Removing Infinities

by our Cosmology Correspondent

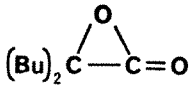
THE infinities which occur both in classical and quantum electrodynamics have disturbed field and particle theorists for decades. The implication that there is some kind of physical limit, or critical length, associated with fundamental particles conflicts with basic dogma, but as the work of Feynman and that of Dyson has shown there is no way to remove the self-mass and self-charge infinities of lepton electrodynamics using the conventional techniques of expanding the mass and charge distributions by a polynomial solution about a point. But by using non-polynomial Lagrangians for small distances the self-mass and self-charge can be made finite.

A group working at Imperial College, London, have been investigating this problem for some time (see, for example, *Nuovo Cim. Let.*, **4**, 101; 1970). C. J. Isham, A. Salam and J. Strathdee have attempted to find a more general solution, modifying Dirac's Lagrangian to take account of gravity as well as electrons and photons, and using a non-polynomial solution. They have now found that the very small range of gravitational forces ($\sim 2{\cdot}2 \times 10^{-22}$ m) does not, as traditionalists have assumed, make them insignificant. From the point of view of the critical length, gravity plays a vital part in quantum electrodynamics.

The crucial discovery by Isham and his colleagues is that their modification makes every Lagrangian in particle physics non-polynomial in character, with the gravitational length providing an inbuilt cutoff and preventing the occurrence of infinities. Conceivably,

the electron self-mass arises from the interaction of its electromagnetic and gravitational properties to produce the electron radius.

To a cosmologist, the most exciting implication of this work (as yet unpublished) is that the gravitational force may be repulsive over very short distances. The agreement of the predictions of this theory with those of Hoyle and Narlikar, who have approached the problem from the gravitational end rather than starting from conventional particle physics, makes both theories more attractive and their implications correspondingly more interesting. The whole question of gravitational collapse (or the lack of gravitational collapse) and the significance of this for cosmology and cosmogony seem once again to have prime importance.



CARBONYL COMPOUNDS

More Small Rings

from our Organic Chemistry Correspondent

THREE-MEMBERED ring carbonyl compounds have frequently been postulated as intermediates in organic reactions. Perhaps the best known example is the intermediacy of α-lactones in solvolysis reactions of α-halocarboxylic acids. Recent attempts to isolate compounds of this type have been successful in the case of the carbocyclic cyclopropanones and with the nitrogen containing α-lactams, but all efforts to obtain an example of the analogous oxygen system, that is, an α-lactone, have been unsuccessful.

The recent report that the lactone (I) of di-t-butyl glycollic acid is stable in solution at −80° C fills this gap in the literature of small-ring compounds (Wheland and Bartlett, *J. Amer. Chem. Soc.*, **92**, 6057; 1970). As with several other small-ring carbonyl compounds, the relatively high stability of (I) is dependent on the shielding effect of the bulky t-butyl substituents. Synthesis of the α-lactone was accomplished by oxidizing di-t-butylketene with ozone, a reagent known to epoxidize highly hindered olefins. In spite of the effect of the t-butyl groups, the α-lactone is no longer stable when the solution (in 'Freon 11') is warmed to −20° C; a white precipitate of polyester $[(C_9H_{18}CO_2)_n]$ separates, the formation of which is probably initiated by equilibrium formation of the zwitterion (II). Molecular orbital calculations indicate that the two structures [(I) and (II)] have similar energies, though spectroscopic evidence clearly rules in favour of (I) as the structure of the species in solution at −80° C.

(I)

(II)

The reactions of (I) are in accord with the character ascribed to α-lactone intermediates in the solvolysis reactions already mentioned, and polymer formation parallels observations on reactions of some peroxides in which α-lactones are also believed to mediate.

Attempts to prepare the diphenyl analogue of (I) from diphenylketene were attended by polymer formation $[(Ph_2CCO_2)_n]$ even at −80° C. Presumably, the phenyl substituents tend to stabilize the zwitterionic structure relative to the covalent α-lactone, but a monomeric species was trapped by carrying out the oxidation of diphenylketene in the presence of methanol, when the product was α-methoxydiphenylacetic acid.

SEA FLOOR SPREADING

Geochemical Effects

from our Geomagnetism Correspondent

SINCE—and even before—sea floor spreading became widely accepted, there have been many attempts to relate geophysical and geochemical parameters to the distance from spreading oceanic ridges. The variation of one such property, the chemistry of the principal elements of basalts, was first reported by McBirney and Gass (*Earth Planet. Sci. Lett.*, **2**, 265; 1967), who showed that the silica saturation of basalts decreases with distance from the ridges and correlates with the decrease in heat flow. To be sure, this was not the first time that differences had been observed between ridge and non-ridge basalts; geochemists have known for some time that ridge basalts tend to be tholeiitic whereas alkali basalts are more likely to be found away from ridges. But McBirney and Gass demonstrated for the first time that variations with distance were systematic.

But do the major elements in basalts always vary with distance from the ridges? And if so, why? To answer these questions, Hart (*Earth Planet. Sci. Lett.*, **9**, 269; 1970) examined the analyses of 112 deep ocean basalts and found that the major elements do usually vary in this way. Thus, for oceanic basalts up to about 18 million years old (the limit of Hart's data), silica, calcium and magnesium decrease almost linearly with distance from the ridges, whereas potassium, iron, titanium, sodium, manganese and phosphorus increase, also approximately linearly. In addition, ferric iron replaces ferrous iron; but aluminium apparently does not change.

Several possible reasons for these variations come to mind. They could arise, for example, from progressive changes in the composition of the magma as it is extruded at the ridge crests. That such changes would be so systematic during a period of 18 million years at least is unlikely, though not impossible. Another possibility is that the basalts have been altered since they were laid down. In view of what amounts to a correlation of major element chemistry with age, this looks like a natural explanation, though deuteric alteration cannot be ruled out *a priori*.

Hart suggests that the variations are produced by alteration through weathering—a hypothesis to which he brings convincing evidence from studies of the weathering of single pillow basalts. In this context, of course, weathering means chemical exchange between the basalts and sea water, though there is still some doubt about whether pillow weathering truly results from subsequent hydration or whether it is deuteric. Insofar as the alteration in pillows is zoned, with the most heavily altered zone on the outside, Hart supports the view that pillows are chemically changed by the water. He then proceeds to compare the changes in the principal elements with those of the deep ocean basalts. The trends are very similar.

If the changes in oceanic basalts really result from long term hydration, geochemists must in future distinguish carefully between true alkali basalts and tholeiitic ridge basalts which have been weathered to

alkali composition. But there is another consequence of deep ocean basalt alteration to which Hart draws attention. This is the overall effect on the Earth's geochemical budget, especially if the extent of weathering is considered significant by virtue of its great depth within the basalt. Elements given off during the basalt weathering will, of course, increase the total supply in the sea water, though some may be taken up by the sediments. Elements absorbed, on the other hand, require a source, which must ultimately be stream runoff from land. It follows therefore that if maximum absorption is to continue the stream supply must be greater or at least equal to that required by the oceanic basalt. In this sense, the most critical elements are titanium and iron, for which the stream supply (using the best estimates at present available) is likely to be insufficient. For these elements, and to a lesser extent manganese and phosphorus, basalt weathering is likely to be the chief control on the geochemical mass balance of the oceans.

PROSTAGLANDINS

More Pharmaceuticals

from a Correspondent

UNTIL recently few people outside the medical and biological world had heard much of prostaglandins, notwithstanding some 1,500 references in the scientific literature of which three-quarters have appeared in the past three years. Then about two months ago the daily and Sunday newspapers began to carry such headlines as "A New Approach to Contraception—the Abortion Pill". The reason for the headlines was not only that prostaglandins had been shown to be usable for this purpose—the scientific fact had been known for some months—but that one large American drug firm, in particular, had announced its intention of moving from fundamental research to the large scale controlled trials needed before the "abortion pill" could be marketed.

Prostaglandins are natural substances with a wide range of biological actions, and their possible physiological, pathological and therapeutic functions are not limited to abortion. A symposium held in London by the Society for Drug Research on November 25 brought together some hundreds of university scientists and industrial pharmacologists to consider some of these possibilities. The survey by Professor J. R. Vane (London) of the fate of prostaglandins infused into the circulation showed that physiological and therapeutic functions of prostaglandins are limited or are perhaps determined by their rapid clearance from the bloodstream *in vivo*. Nevertheless, as Professor V. R. Pickles (Cardiff) showed, endogenous prostaglandins from the endometrium almost certainly act physiologically as part of the normal mechanism of menstruation, and may be involved in the causation of dysmenorrhoea or "period pains". The use of exogenous prostaglandins for the induction of labour or therapeutic abortion is perhaps derived from this physiological observation, and Professor S. M. M. Karim (Kampala) gave details of his large series of such cases.

Prostaglandins may also be involved in inflammatory reactions of various kinds, for example, in the skin, and in the eye, which is one of the sites where their occurrence was first noted. In the lungs, some members of the group cause bronchoconstriction (as in asthma), whereas others have an opposite effect which may be turned to therapeutic advantage. In various glandular tumours the occurrence of prostaglandins seems to be irregular but intriguing. Investigation is hampered by the continued absence of very potent and specific antagonists, but at least three groups of compounds show some activity of this type and further advances will doubtless be made.

It was made clear at the symposium that fundamental physiological and biochemical research is still needed and perhaps there is a place still for the small university team, though opinions differed on whether lack of gas–liquid chromatography with mass spectrometry facilities necessarily precludes all attempts to identify or assay prostaglandins in tissue extracts. There can, however, be little doubt that proper identification of prostaglandins in the sub-micromolar concentrations in which they appear in tissues poses considerable problems and many claims of identification by simple means could be checked by the more precise physico-chemical methods. Again, proposed mechanisms of prostaglandin action at the molecular level—such as the suggestion of Dr J. R. Smythies (Edinburgh) that they are involved in agonist–receptor interaction in the nervous system and elsewhere—may best be tested by using the prostaglandin analogues developed by drug firms.

REPRESSORS

Clothing the Naked Gene

from our Molecular Biology Correspondent

THE *lac* operon is now perhaps better known as a vehicle for the cultivation and public display of tender social consciences than merely an interesting topic (in this year's parlance, paradigm) in molecular biology. Among the aspects of scientific interest that still adhere to it, and one which will not, one may hope, strike terror in the populace at large, is its interaction with the repressor. The nature of this process has been studied by Gilbert and Müller-Hill, and by Riggs and his associates. Its kinetic features have now been explored by Riggs, Bourgeois and Cohn (*J. Mol. Biol.*, **53**, 401; 1970). They use a membrane-filter method for determining the instantaneous concentration of the complex, based on the observation that free but not complexed DNA passes the filter. When a large excess of unlabelled DNA is added to a sample of labelled DNA saturated with repressor, exchange occurs at a rate determined by the concentrations, and the lifetime of the complex. The rate equation for replacement of labelled by unlabelled DNA in the complex then contains two terms, one expressing the rate of dissociation, the other of association. As long as the concentration of free repressor is low, which is assured by a large overall excess of DNA, the second term can be disregarded, and the reaction follows first-order kinetics, with a rate constant of the order of $10^{-3}-10^{-4}$ s^{-1}, depending on ionic strength, the time scale of the experiment being some 30 min.

The forward reaction is measured directly, at very low DNA and repressor concentrations. The corresponding second-order rate constant is 10^{10} M^{-1} s^{-1}. Everything fits in with this straightforward kinetic scheme, and in particular the ratios of the forward and reverse rate constants under different conditions are in excellent agreement with the corresponding equilibrium con-

stants for the association, measured independently and directly.

The results have considerable bearing on the nature of DNA–protein interactions in general, and highlight the rudimentary state of knowledge concerning such processes. In the first place, the forward rate constant is extraordinarily large—greater, as the authors note, than can easily be accounted for even in terms of a diffusion-limited reaction. The electrostatic component, which the ionic strength-dependence shows to be present (even though the repressor has an overall negative charge), does not seem of overwhelming importance. It has always seemed generally most reasonable to view DNA–protein interactions of high specificity as proceeding through the single-stranded state, which becomes available in virtue of the supposed "breathing" relaxation of the double helix. Riggs *et al.* argue that in this instance such a mechanism is excluded by the reaction rate. Denatured DNA moreover does not react. The results therefore demand a re-examination of some preconceptions about the mechanism of recognition of proteins by DNA. The repressor may in this case interact with the exiguous portions of the bases exposed in the large groove.

Another example of very strong binding occurs in the colicinogenic factor of *Escherichia coli*, which is a DNA containing body, separate from the chromosome. Clewell and Helinski (*Biochemistry*, **9**, 4428; 1970) have established a number of interesting features of this material. It consists of a DNA supercoil, containing a tightly bound protein component. On treatment with detergents or proteolytic enzymes, the hydrodynamic properties change in a manner that betokens the unwinding of the supercoil. The minor fraction of uncomplexed supercoiled DNA that is present does not respond to this treatment. Two mechanisms for the action of the protein now suggest themselves: it may be a nuclease, which breaks one DNA strand, a single nick being known to be sufficient to release the tension responsible for supercoiling. Alternatively the nick may be present in the complex, but not manifested because the ends are prevented from separating by the bound protein, until this is denatured or degraded. Clewell and Helinski, however, find that if the cells are heated before lysis, intact uncomplexed supercoiled DNA is isolated, suggesting that the nick is not there all along. A further relevant finding follows from hybridization experiments, which show that the nicking reaction is specific to one of the strands. What lends this work especial interest is the current view that the introduction of a nick by an inelegantly termed "nickase" precedes the normal initiation of replication.

TUMOUR VIROLOGY

Susceptibility to Transformation

from our Cell Biology Correspondent

In 1966 and 1967, Todaro and his colleagues reported that cultivated human fibroblasts taken from patients suffering from Franconi's anaemia and Down's syndrome were more susceptible to transformation *in vitro* by simian virus 40 than corresponding cells from healthy persons, and the work of Mukerjee and his colleagues suggests that this finding also applies to cells from patients with Klinefelter's syndrome. These three diseases are associated both with a higher than usual incidence of chromosomal abnormalities and with cancer. It may well be that all the diseases involve some defect in cellular replication which results in the production of chromosome abnormalities, the increased susceptibility to cancer and the SV40 transformation. These findings have, not surprisingly, led to the suggestion that a measure of the susceptibility of a person's cells to transformation *in vitro* by SV40 might be used as an indicator of that person's relative risk of developing cancer. Clearly therefore there is more than academic interest to discovering why some human cells are more readily transformed than others.

Pursuing this question Aaronson (*J. Virol.*, **6**, 470; 1970) has repeated Todaro's experiments using naked SV40 DNA as well as intact SV40 particles as transforming agent. He finds that with SV40 DNA the differences in susceptibility to transformation between various human cell strains are eliminated; human fibroblasts which differ by a factor of a hundred in their susceptibility to transformation by SV40 particles are equally susceptible to transformation by SV40 DNA. This result implies, of course, that the relative resistance or susceptibility of a particular cell depends on some block, or lack of it, to an early event in infection.

Virus-specific T antigen appears early in infection with intact SV40, and those infected cell populations which have the highest proportion of cells containing T antigen are also the populations with the highest transformation rates. But when SV40 DNA is used, populations of various cell strains have the same fraction of cells staining for T antigen as well as the same transformation rates. This again indicates that differences in the transformation rates between susceptible and resistant human fibroblasts are the result of some failure, in the resistant cells, of an early event in infection—either a failure in adsorption, penetration or uncoating of the virus. Aaronson has now eliminated the possibility that resistant cells fail to adsorb the virus, or adsorb less of it than susceptible cells. Further, he has shown that when sensitive or resistant cells are infected with adeno-SV40 hybrid virus, which contains only part of the SV40 genome but includes the gene(s) responsible for the induction of T antigen, SV40 T antigen appears in the same fraction of populations of both sorts of cells. In other words, the block to T antigen production which is apparent when SV40 infects a resistant human fibroblast does not block the induction of the T antigen by SV40 genes enclosed in an adenovirus capsid. It seems likely therefore that the resistance or susceptibility of human cells to transformation by SV40 depends on some block, or lack of a block, to the uncoating of SV40 and, moreover, this block is specific for SV40. Clearly the correlation between susceptibility to cancer and to transformation by SV40 deserves further investigation.

Aaronson (*J. Virol.*, **6**, 393; 1970) has also been investigating the sensitivity to inactivation by ultraviolet light of three functions of the SV40 genome; its ability to transform, to induce T antigen and to induce capsid antigen. Transformation seems to be the least sensitive of the three functions. These experiments also support the suggestion that the induction of T antigen and of transformation are closely related. After initially diverging, the slopes of the survival curves for T antigen induction and transformation run parallel and all the cells transformed by the irradiated virus contain T antigen.

Season of Birth and Cognitive Development

by
PHILLIP WILLIAMS*
PAT DAVIES
ROY EVANS
NEIL FERGUSON

Schools Council Research and Development Project in Compensatory Education, Department of Education, University College of Swansea

Certain groups of handicapped children clearly contain a high incidence of those born in the summer. The fault seems to lie with the British educational system.

THE relationship between human development and season of birth has been the subject of numerous enquiries—in reviewing earlier work, Fitt[1] suggested that the slight advantages in various aspects of development, including intelligence, enjoyed by children born in the summer–autumn seasons in either geographical hemisphere were a consequence of seasonal influences on conception. Later work has not always supported this conclusion. Jessup and Freedman, in a carefully analysed enquiry presented at the annual conference of the British Psychological Society in 1967, found a "trough" in the measured intelligence of children born during February–May and a less clear peak in the measured intelligence of those born during the October–November period—a finding somewhat out of phase with Fitt's conclusions. Berglund[2], working with Swedish children, found no evidence of a difference between the intelligence quotients of those born in different seasons. Ojha *et al.*[3] found no relationship between season of birth and intelligence among a sample of university entrants. Orme[4,5], working with severely subnormal adults, found a preponderance of summer-born and autumn-born individuals in the more intelligent section of his population. He considers the May–October birth season to be intellectually advantageous. Farley[6], reporting a study of a group of apprentices, concluded that there was likely to be little support for season of birth effects in normal populations. It seems to be difficult to show a clear relationship between intellectual development and season of birth except for large or special populations and even then findings are not always consistent.

There is a considerable body of evidence that in Britain there are differences of educational development between children born at different seasons of the year. Children born in the summer months undoubtedly attain lower educational standards than children born at other times of the year. This applies when chronological age is held constant, through the use of standardized attainment tests, for example. Pigeon and Dodds[7] demonstrated this with junior school children, and Jinks[8] showed how children born in summer were likely to be found more frequently in the lower streams of junior schools than would be expected on the basis of their frequency in the population under study. France and Wiseman[9] found that the performance of the children on which the eighteen tests of their educational guidance programme for primary school children were standardized varied according to the season of the year. Children born in autumn (September–December) had slightly higher scores than those born in spring (January–April), who in turn had slightly higher scores than those born in summer (May–August). This breakdown of the year into three sets of four months is an arbitrary division which mirrors the school year. It is, however, a division which has been used in previous studies, and we shall use it in this article. The differences between the performances of children born in the three periods of the year were small but significant. The findings of France and Wiseman can be regarded as a useful quantification of Jackson's observations[10] that children born in summer tend to predominate in the lower streams of streamed schools (and that the larger the school the greater the concentration of summer-born children in the lowest streams).

France and Wiseman also drew attention to the fact that the differences between children born in different seasons diminish with age. This may be one reason why investigators working with older school populations have not found the effect. Thus Armstrong[11] found no relationship between season of birth and success in the "eleven plus" examination for grammar school entry. Neither did he find any significant difference in O-level examination results for older children born at different seasons of the year.

Armstrong's criteria provide other reasons for the failure of this enquiry to agree with earlier work. Both criteria (success at eleven plus and O-levels passed) differentiate between and within groups of individuals who are of well above average performance. Similarly, Ojha's enquiry, which confirms Armstrong's findings, is concerned with a population well above average in educational development. These findings are thus not necessarily inconsistent with those noted earlier and which do exhibit differences between the performance of primary school children in accordance with season of birth.

Educationally Handicapped Children

With populations of low educational development a much clearer picture emerges. John[12] found a significantly higher proportion of summer-born children among retarded readers than would have been expected. Williams[13] and Griffiths[14] reported similar findings. Williams[13] and Bookbinder[15] demonstrated a preponderance of summer-born children in schools and classes for the educationally subnormal (ESN) or slow learners.

The effect is also clearly present in children whose handicap is psychological, rather than educational, that is when the deviance is in behaviour rather than educational development. The existence of a summer birthday effect among children referred to child guidance clinics is mentioned in Williams[13], and Lloyd[16] notes the presence of the same effect among boys at a remand home.

It is interesting to note the extent to which children born in summer predominate in the various groups of handicapped children studied. It is possible to extend the

* Present address: Faculty of Educational Studies, the Open University, Bletchley, Buckinghamshire.

table reported by Williams[13] to show how more recent findings emphasize the consistency of the preponderance of children with summer birthdays in populations of handicapped children.

A child born in summer seems to have approximately a 50 per cent greater chance than a child born in autumn of some form of special treatment. It is important to try to establish the reasons for this greater risk.

Possible Causes of the Effect

Because of the inconsistent findings relating to intelligence level and season of birth we shall deal only with the clear and consistent relationship between season of birth and risk of membership of one of the groups of children with educational and behavioural handicaps described in Table 1.

Table 1. SEASONAL BIRTHDAY DISTRIBUTION OF HANDICAPPED CHILDREN

Group investigated	Ref.	Season of birth Autumn	Spring	Summer	No.
Retarded reader	12	27	32	41	1,600
	13	27	35	38	382
	14	23	33	44	128
ESN children	13	25	33	42	265
	15	26	33	42	1,289
Child guidance cases	13	28	35	37	1,511
Boys on remand	16	32	25	43	82

Figures are percentages.

The explanations suggested for the preponderance of summer-born children in these groups have been based on the organization of the school system. Two alternative explanations have been compared. One, the "term of entry effect", suggests that children born in summer are at a disadvantage because "they spend a shorter time in their infant schools than do children born at other times of the year". This was one of the reasons which led to the Plowden committee's recommendation[17] of a uniform date of entry to infant schools or first schools, so that all children spend a full three years there. The other explanation, also noted by Plowden, is the "age group effect". This suggests that the children born in summer are at a disadvantage because in the British educational system they are usually the youngest in their school age-group and may find school more of a strain than children born at other seasons.

These two effects can be separated by looking at the incidence of birth months within separate school terms. Williams[13] suggested that the age-position effect might be the more important in determining the preponderance of the summer-born in his population of ESN children and Bookbinder[15] demonstrated this clearly. The "term of entry" effect seems to be of little importance. Pigeon[18] points out that in Sweden, where children enter schools once a year and not by term, a seasonal variation in attainment still occurs and can be attributed to age group position effect. The interesting point of the Swedish situation is that their age groups are of different composition from those in England and Wales. Berglund[2] comments that the autumn-born children in Sweden are the youngest in their age group and not the oldest, as is the case in England and Wales. Thus if the age-group position effect is operating, in Sweden children born in autumn should be preponderant among those with learning difficulties. Berglund's figures relating to his population of Swedish children attending backward classes can be reanalysed to show the relative incidence of children with different seasons of birth. In accordance with prediction a high incidence of autumn-born children is found (Table 2, taken from ref. 2).

Table 2. SEASONAL BIRTHDAY DISTRIBUTION OF BACKWARD CHILDREN

	Season of birth Autumn	Spring	Summer	Total
No.	91	76	70	237
Per cent	38	32	30	100

It seems likely that age-group position effects are responsible for the high incidence of summer-born children with learning difficulties in the educational system in England and Wales. As Pigeon says[7], "While the possibility may exist that children born in the warmer summer months may obtain slightly higher scores in intelligence tests, there is little doubt that the advantages gained by these children are small compared with the disadvantages conferred on them by being born at the wrong end of the school year."

These disadvantages may also account for the high incidence of summer-born children in populations of child guidance and court cases reported in Table 1. The additional strain imposed by a difficult school situation may well be a cause of behaviour problems which lead to referral to a child guidance clinic or to a court appearance. The negative relationship between educational attainment and maladjustment, (for example ref. 19) and delinquency (for example ref. 20) is well known.

Another possible explanation relates to seasonal birth rates. The variation between birth rates at different seasons of the year is small in comparison with the differences found in the distribution of birthdays of handicapped children; most of the enquiries we have mentioned allowed for this. (Usually the birth rate during September to December is a little lower than in the other two periods: Bookbinder[15] reports ratios of 31 per cent: 34½ per cent : 34½ per cent for September–December: January–April: May–August in Bristol. Lawrence *et al.*[21] give figures for South Wales which can be evaluated as 32 per cent : 34 per cent : 34 per cent for the same periods.) It is possible, however, that there is a differential seasonal fertility between the social classes. If the lower social classes, which are more "at risk" educationally, are more likely to have summer-born children than the middle and upper social classes, this may partly or wholly account for the preponderance of summer-born children in these special groups, quite apart from any educational factors.

The Registrar General (personal communication) provided an unpublished tabulation of the breakdown of births by social class by month of birth. The figures related to a 10 per cent sample for the period July 1963 to June 1964. Table 3 is calculated from these figures.

There is thus no indication that social classes IV and V are more likely to produce children in summer than are social classes I, II and III.

Another important possibility is the existence of a congenital learning disability which is linked to season of birth. There is little evidence that congenital physical disabilities are linked to season of birth. Lawrence *et al.*[21] found that in a large population of children born with malformations of the central nervous system, conception was less frequent in April, May and June than expected. Lawrence points out that this finding is not consistent with

Table 3. SEASONAL BIRTHDAY DISTRIBUTION BY SOCIAL CLASS

Social class	Season of birth Autumn	Spring	Summer
I	30	35	35
II	32	35	34
III	31	34	35
IV	32	34	34
V	32	34	34

Table 4. VECTOR LOADING IN CANONICAL CORRELATIONS

Solution	Canonical correlation	Vector loading of month of birth
1	0·54	−0·04
2	0·33	+0·03
3	0·31	−0·02

other work in the same area. It is, however, an interesting possibility that congenital factors affect the learning ability of children born in the summer in Britain, leading to their preponderance in special educational groups. One way of testing this is to examine the psychological development of a group of children at the time they enter school in order to see if there is any significant over-representation of summer-born children among less able individuals. If there is such an over-representation, then it is reasonable to conclude that the over-representation of summer-born children in the deviant groups of Table 1 cannot be due solely to the influence of the education systems, and that we must look for other factors such as congenital factors. These factors could of course operate as well as, or instead of, educational influences.

part of a further analysis of the data, canonical correlations were computed between the fourteen developmental variables and eight predictor variables. Seven of the predictor variables were measures of aspects of the child's home background. The month of birth was the eighth variable.

Probability tests indicated that significance could only be attached to the first three canonical correlations. The vector loadings of month of birth for each of these three solutions were as in Table 4.

Clearly the child's month of birth plays a negligible part in the solution of the interrelationships between the two sets of data.

Although the results are not positive, the data may conceal a relevant effect. So far we have considered relationships between month of birth and the developmental levels of all the 695 children. Although relationships may be negligible in the total sample, there may be an effect at the extremes of the sample. This is the point that Wiseman[22] makes when he refers to the importance of splitting the variance to examine correlations in different sections of the distribution. We illustrated the point when our review of research revealed consistent findings for groups of handicapped children—children at the extremes of the population—but inconsistent findings for the population as a whole.

Table 5. DISTRIBUTIONS OF MONTH OF BIRTH OF SAMPLE CHILDREN

Data Available for our Enquiry

The Schools Council Research and Development Project in Compensatory Education is primarily concerned with the production of materials for deprived children. During this process considerable research data have accumulated. The identification techniques unit has been developing materials for the early identification of children at risk when they enter infant schools, and this work has involved the assessment of a judgment sample of 695 school entrants. Some characteristics of this sample have been described by Evans *et al.* (unpublished work). For the purposes of this article it is sufficient to say that the sample under study is drawn from two different areas, a Midland conurbation and a Welsh county. It consists of the intake in the school year 1968–1969 to twelve infant schools, eight in deprived areas, two in settled working class areas and two residential schools. The sample is likely to contain a higher proportion of slow learners than a randomly chosen sample, in view of the bias towards schools in deprived areas.

The children were all assessed with fourteen short developmental tests as part of a wider programme. The tests took about an hour to administer to each child and included measures of language development, non-verbal ability and perceptual and motor skills. The intention of assessing all children within a month of school entry was not met, but more than 94 per cent were assessed in their first term. There was nothing to suggest the existence of a relationship between birthday and late or early assessment. The relationships between the data on development and month of birth were then analysed.

First the product-moment correlation coefficients between each of the fourteen developmental variables and month of birth were noted. These ranged from a maximum of +0·06 to a minimum of −0·05. All are negligible and none is significant.

Although the straight correlation coefficients do not give positive results, it is possible that the multivariate nature of the data conceals other interesting relationships. As

The first problem was to find a satisfactory combined score for the fourteen variables on which the children had been assessed. We decided to carry out a principal components analysis of the relationships of the variables. The first principal component accounted for 54 per cent of the variance, and seemed to be a general component on which most of the variables loaded positively. The children were ranked by score on this first component, and the bottom seventy children were noted. These children could be regarded as developmentally the weakest—the least able 10 per cent of the sample of 695 entrants to infant schools.

The months of birth of these seventy children were extracted and compared with the expected distribution of month of birth, based on that of the total 695 (Table 5). Condensing the twelve months into the conventional four month periods and calculating the expected frequencies of occurrence in a sub-sample of seventy on the basis of the distribution in the 695 we produce Table 6. Clearly there is no real suggestion of any preponderance of children born at a particular time of the year among the weakest entrants to infants schools. A similar analysis for the weakest 140 children produced similar findings.

Table 6. OBSERVED AND EXPECTED DISTRIBUTIONS OF MONTH OF BIRTH OF SEVENTY WEAKEST CHILDREN IN SAMPLE

Observed	25	26	19	70
Expected	29	24	16	70

Implications for the Educational System

The findings of this study show no evidence of a "season of birth" effect among five year old children entering the British school system. It is considered not unreasonable

to have expected such an effect to have shown up in a sample of this size and composition. This result strengthens the view that the "season of birth" effect in handicapped children is likely to be a product of the educational system itself. This cannot be a conclusive finding, but we suggest that it is a probable one.

This leads to a consideration of the ways in which the education system could be modified to reduce the incidence of handicapped children among the summer-born to that existing among winter-born children. The resultant easing of pressure for places in schools for slow-learners, for the maladjusted, and so on would make a tremendous difference to the services dealing with handicapped children.

The evidence of the research findings we have discussed suggests that, contrary to widely held views, the term of entry effect is not responsible. The Plowden report, for example, recommended that there should be a uniform date of entry to infant schools, or first schools, so that all children should spend an equal amount of time there before moving on with their age group to junior or middle schools. There may be other reasons for suggesting this equal length of infant education, but research evidence does not suggest that it will remove the extra educational handicaps which summer-born children carry. It is unlikely to result in any improvement of the educational lot of the summer born. It is not more education that is needed, but different education.

We suggest that it is the age group position effect which must be the target of educational expenditure if this problem is to be eased. There are humanitarian and economic reasons for an attempt to deal with the problem. Even if we are prepared to put on one side the humanitarian pressures to reduce the number of slow learners, for example, there is still the economic argument that such a reduction might more than repay the money invested in producing it.

Any proposals which decrease the need to treat a class of children as a unit should be encouraged. The need to proceed at the pace of the class places strain on the intellectually immature. And, *ceteris paribus*, the intellectually immature are likely to be the younger children. Greater flexibility in arrangements for retaining summer-born children in classes of younger children, more use of vertical grouping, smaller classes, a wider availability of school psychological services are not new proposals. But they direct attention towards the individual and his needs and away from the group. Our principal conclusion is that resources spent in this way are likely to be much more effective in providing a fairer educational deal for the summer-born than resources spent in giving all children the same length of time in school.

Thin Film Research Today

by
O. S. HEAVENS
Department of Physics,
University of York

Improved methods of study have contributed to a great advance in thin film research in the past twenty years. A brief survey shows that applications have spread to many advances of electronics and optics.

One manifestation of the growth of the importance of thin film and surface studies has been the emergence, during the past few years, of three specialist journals (*Surface Science*, *Thin Films* and *Thin Solid Films*). Until the end of the Second World War, only moderate effort was devoted to such studies and the technological importance of films was confined to a few fields such as electroplating and, in a limited sense, optics. In the past twenty years, there has been an enormous growth of activity, both in basic studies of film properties and behaviour and in the introduction of thin film technology to a host of industrial applications. In this article I shall discuss a selection of such applications.

In the past few years, methods of studying film growth and structure have improved considerably. Electron microscopy and diffraction, operated using high energy (tens of kilovolts) electrons, have been supplemented by the development of low energy electron diffraction (LEED) and Auger emission spectroscopy. At the same time the impressive advances in ultrahigh vacuum techniques have led to the situation where, for the first time, experiments can be done in known, controlled conditions. Many of the uncertainties which led to difficulties of interpretation of early measurements have been removed. In one sense, the problems associated with film studies start before the film is formed. The precise surface structure of the supporting substrate can often exert a decisive influence on thin film properties. By the use of LEED and Auger techniques, essential basic information about the nature and structure of substrate surfaces

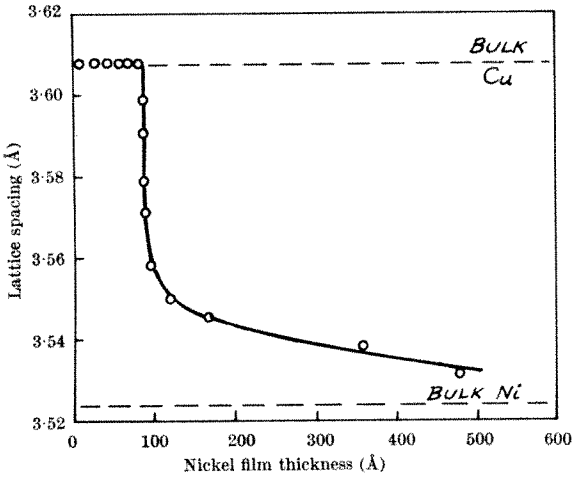

Fig. 1. Variation of lattice parameter of nickel deposited on copper substrate.

can be obtained. Moreover, the availability of ultrahigh vacuum systems makes it possible to carry out experiments without uncertainties created by the influence of residual gas in the vacuum system. Another powerful tool is the mass spectrometer, which facilitates studies of adsorption and desorption phenomena.

As was the case with the study of bulk solids, progress became very rapid when single-crystal materials were studied. Investigations of films were greatly aided by the phenomenon of epitaxy, which is a fascinating, and in some respects still perplexing, subject. For a long time it was a mystery that epitaxy could occur readily between a film and substrate even in the face of very large misfits between the lattice constants of the substrate and deposited materials. At an early stage, the idea of pseudomorphic growth was proposed, by which the lattice spacing of the deposit material was supposed to be strained to that of the substrate. Early experimental difficulties made it impossible to confirm this idea, but it has now been established that pseudomorphic growth does occur in some conditions. Fig. 1 (taken from ref. 1) shows that the lattice spacing of epitaxial nickel on a single crystal copper substrate is strained to that of the substrate for thicknesses up to 80 Å, beyond which the spacing rapidly approaches the normal value for bulk nickel.

Nucleation of Films

The very difficult problem of nucleation of films at the onset of growth has received considerable attention in recent years. The classical theory of homogeneous nucleation gives some general guidance but there are two principal difficulties. On the one hand, the quantities in terms of which the theory is expressed, such as interfacial energies, diffusion rates and surface energies, are difficult to measure and generally impossible to calculate. On the other hand, the theory shows in some cases that the critical size of nucleus (below which growth cannot proceed) contains only a few atoms. The problem thus arises of justifying the use of macroscopic thermodynamic concepts to a system containing so few atoms. Hirth, Hruska and Pound[2] have developed this ("capillarity") model to an impressive level, including the effects of desorption and surface diffusion. In their view, the theory can be expected to give reasonable results for nuclei containing more than about 100 atoms. The problem of very small critical nuclei has been tackled by Rhodin and Walton[3] in a theory of heterogeneous nucleation, which shows that the size of the critical nucleus can be obtained from the dependence of nucleation rate on temperature. Indirectly, this gives indications of the likely orientation of critical nuclei, which is important in considering epitaxial growth.

In view of the fact that surface defects serve as nucleation sites, useful information can be gained from studies of films grown on surfaces subjected to electron bombardment. Several groups are actively engaged on this problem, which is still at the stage where stimulating arguments on interpretation are the rule.

There seem to be two skeletons in the nucleation/film growth cupboard. In a cinemicrograph of a growing film, Pashley has observed that very large crystallites can be very mobile, skating rapidly across a surface to coalesce with larger, fixed ones. This is both difficult to understand and difficult to build into existing theories. The second problem arises from Barna's[4] observation that epitaxy can occur on an amorphous carbon film, deposited on a monocrystal, even for thicknesses of carbon up to 100 Å. Both these observations tend to underline the simplicity of current approaches to problems of film growth: no simple adaptation of present models seems to account for this unexpected behaviour.

Improvements in the performance of the electron microscope, which can now resolve lattice planes of simple structures, have led to rapid developments of dislocation theory, much of which has derived from the use of epitaxially grown films. The movement of dislocations has been observed by straining specimens *in situ* and considerable progress has been made in the understanding of the strength of materials. In view of the limited extent to which dislocations in a thin film can move, the mechanical strength of films would be expected to increase with decrease of thickness. This is indeed observed in measurements of the fracture strength of silver, as shown by the results in Fig. 2 (from ref. 5).

The use of low energy electrons for diffraction experiments has brought enormous advantages for surface studies. Because the penetration of slow electrons extends only to a very few atomic spacings, it is certain that the information carried by the scattered electrons refers only to the surface layers. In spite of some difficulties on the theoretical side, which limit the full exploitation of this technique, much information can be

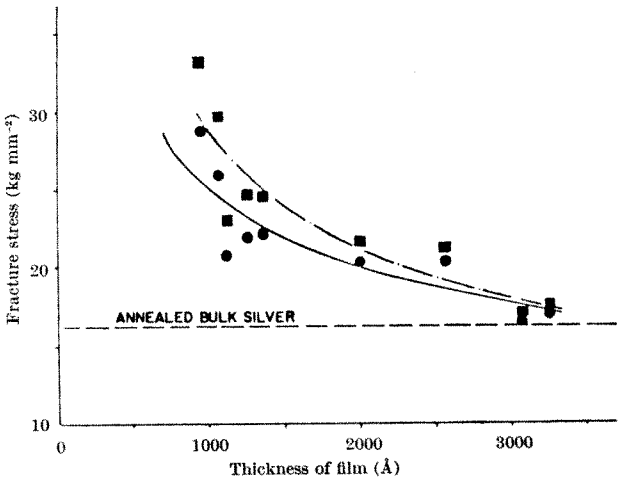

Fig. 2. Dependence on thickness of the fracture strength of silver film (reproduced by courtesy of the editor of *Thin Solid Films*). ●, As deposited; ■, corrected cross-section.

obtained about surface structures. The results have already demolished various preconceived notions on the nature of ("well understood") crystal surfaces. It should not, however, be thought that high energy diffraction has become *passée*. In addition to its continuing role in the determination of structure and orientation of individual microcrystals, it has been exploited in the study of the electronic properties of alloys. Certain alloys have superlattice structures with very long periods (for example, 40 Å for CuAu II). Study of the periodicity in such superlattices as a function of the number of free electrons and of the mass and size of constituent atoms can provide details about the electronic properties of the alloys, leading to information about the Fermi surface. For this work, many single-crystal specimens of various compositions are needed. The time and effort required to prepare bulk samples would be prodigious: the growth of films of such materials by epitaxy is a trivial problem[5].

Optical Uses

The physical properties of materials in film form which have evoked the greatest interest are optical, magnetic and electrical. Optical studies have led to the development of optical filters with remarkable characteristics: magnetic studies have produced computer memories which are much faster than existing ones, and electrical studies have led to the rapidly developing fields of thin-film microcircuitry and integrated circuit technologies.

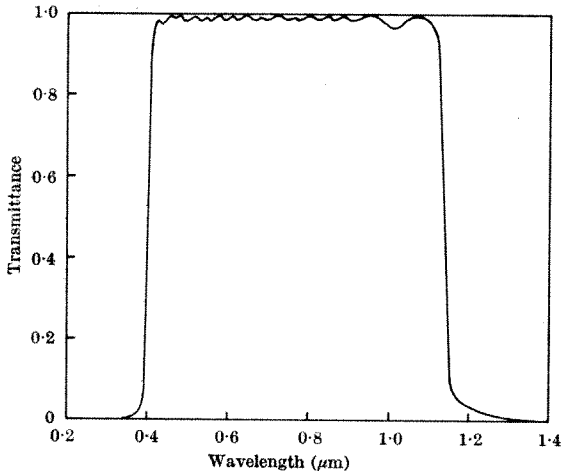

Fig. 3. Transmission curve of filter for use with solar cell.

Since the early days when the now familiar blooming layer on a lens surface was used to reduce unwanted reflexion, filters with stacks of dielectric layers have been developed to an impressive level of performance. Multilayer filters of this type have played a decisive part in the development of many instruments and devices. Thus the operation of the commonest gas lasers relies entirely on the availability of high reflecting layers which may reflect more than 99·5 per cent of the incident radiation and yet transmit a substantial part of the remaining energy. Moreover, such reflectors can be designed to have a high reflectance at one wavelength and a very high transmission at another. An important development has been the production of the second harmonic of a laser frequency by the use of a non-linear crystal. This requires a system which transmits the fundamental frequency so that the exciting radiation can get into the crystal, but which has a high reflectance at the second

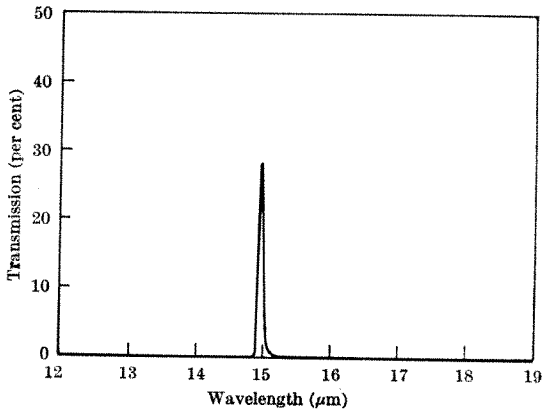

Fig. 4. An example of a narrow-band filter for the infrared (reproduced by courtesy of Grubb Parsons Ltd).

harmonic frequency. This is easily achieved with a multilayer system.

Solar Cells and Holograms

The silicon solar cell plays a vital part in providing power for artificial satellites, through the direct conversion of solar into electrical energy. Such cells have a response over a limited band (0·4 to 1·1 μm) but their efficiency decreases seriously with undue rise of temperature. Because substantial amounts of solar energy are contained in the region outside this band, filtering is essential to exclude unwanted wavelengths. A 62-layer system designed for this purpose has the characteristic shown in Fig. 3. The transmission over the band of interest exceeds 96 per cent. Multilayers have also developed impressively for use in narrow-band filters (Fig. 4). The development of instruments has benefited because a simple filter and detector can replace a more complex and costly dispersing system.

Holography provides another important optical application of thin films. Since the arrival of the laser holography has grown rapidly, with impressive results. But it has been clear for some time that, from some points of view, the photographic plate has serious limitations as a recording medium. Recently, holograms have been produced using a glass plate coated with a metal film, such as Bi, Al, Au, which is vaporized by the action of the

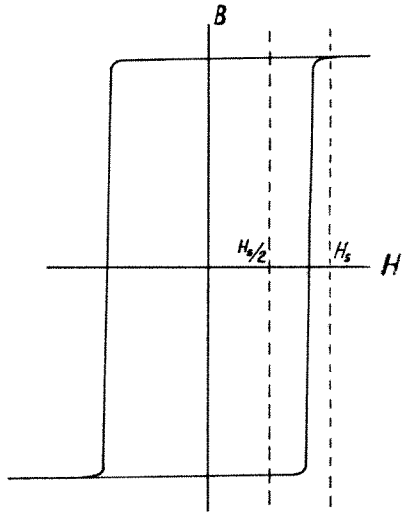

Fig. 5. Magnetization loop for a thin permalloy film.

(two) laser beams from the holography set-up. In the most intense parts of the light pattern forming the hologram, most metal is removed. Thus the transparency of the hologram varies with the illuminating beam intensity as desired. The resolution obtained is comparable with that of a photographic plate; no processing of the metallized plate is needed after exposure.

Magnetic Applications

Studies of magnetic properties of films have been important not only for fundamental theories of ferromagnetism but also as vital elements in modern methods of digital storage. Thin film elements can easily be made which display nearly rectangular hysteresis loops. Fig. 5 shows that the magnetization is unchanged by the application of a field $H_s/2$ but its direction is reversed by a field H_s. The device therefore lends itself readily to the construction of a storage array in which the state of magnetization may be read or changed by the application of current pulses to a pair of conductors which intersect at the element in question. This is essentially the technique used with the existing ferrite core of the computer store. The access time for the present ferrite core store is about 0·5 μs and it is difficult to see how any substantial reduction can be achieved. For the magnetic film store, the access time is approaching one hundred times smaller than this, thus providing potentially much faster computer systems. (So far, this very high speed cannot be utilized effectively, for it is limited by the speed of other parts of the system.) In another form of magnetic storage element, the film is deposited on a wire, which also serves as one of the access channels (Fig. 6).

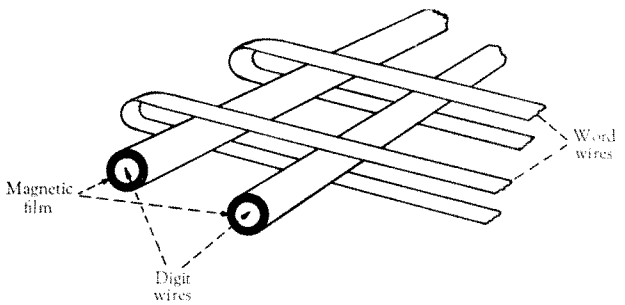

Fig. 6. Plated wire storage element.

Looking ahead, it seems likely that another magnetic effect—the magneto-optical effect—may provide a future generation of data-handling devices. Changes in magnetization of thin films of ferromagnetic materials can produce changes in the state of polarization of light transmitted or reflected by the system. Thus a laser beam can be used to scan arrays of such elements, the information being read from the state of polarization of the light leaving the specimen.

Electrical Applications

So far as electrical behaviour is concerned, the polycrystalline film, particularly of metals and semiconductors, is an extremely complicated system with various possible conduction mechanisms. Thus the ultra-thin metal film, consisting not of a parallel sided layer but of a scatter of isolated crystallites, may conduct through the effects of the substrate or through tunnelling between crystallites. The individual crystallites will not, however, behave like the bulk material because their size will generally be less than the electron mean-free path: the effects of surface scattering will therefore dominate. With the improvement in experimental techniques, understanding of the electrical behaviour of metal films is increasing rapidly although it is by no means complete. The conducting properties of semiconducting layers—once a bewildering set of results—are beginning to be understood, notably through the contribution of Hill[7], who has shown that, for many materials, the assumption that Poole–Frenkel defects dominate leads to results which agree with experimental results over eight orders of magnitude in the conductivity.

It was soon realized that thin film systems offered great promise for the construction of microcircuits. Evaporation techniques for metals and dielectrics easily lent themselves to the production of resistors and capacitors of very small bulk. Moreover, the associated large surface to volume ratio made these systems attractive from the standpoint of heat dissipation. Other techniques, such as reactive sputtering, photodissociation and photopolymerization, have also been used to produce films for electrical circuitry.

With the rise of semi-conductor technology, the emphasis on thin film circuitry has shifted from that in which individual components are produced and joined together, to that in which truly integrated circuitry is achieved. Thus the transistor, instead of being a separate, wired-in component, is made on the silicon substrate surface, with associated resistors, capacitances and connexions, by a range of techniques, including evaporation, sputtering, oxidation and heat treatment stages.

Photoresist is now widely used as a means of producing a suitably metallized pattern on the silicon surface. The surface of the silicon is coated with a film of the required material which is in turn coated with a layer of photoresist. On exposure to a light pattern, the resist can on development be selectively removed from the light parts (positive resist) or dark parts (negative resist) of the pattern. The underlying film can then be removed selectively over the areas from which the resist has been removed. By these methods, an enormous density of components can be achieved on a chip. The typical size of, for example, a transistor made by these methods is a few tens of micrometres. The advantage of this approach is not only size but also the fact that the circuits can operate at far higher frequencies than can their predecessors.

In this necessarily brief survey of interest in thin films, little more than a general indication can be given. On the more basic side, the development of new and powerful methods of studying films has led to a situation where many of the uncertainties surrounding early work can now be removed, and rapid progress is being made. Also the improved methods of control of deposition parameters and of film structures have led to the rapid exploitation of many of the important technological benefits to be had by the use of thin film systems.

Several amino-acid positions in the light chains of rabbits are different from the same positions in the light chains of man. This observation suggests that rapid gene expansion is a fundamental mechanism in the evolution of the immune system.

INSIGHT into the mechanism responsible for antibody diversity has been provided in the past few years by the amino-acid sequence analysis of homogeneous immunoglobulins produced by plasmacytomas in man[1–5]. These studies have shown that immunoglobulins are composed of light chains (molecular weight 23,000) and heavy chains (55,000) which are linked through disulphide bonds. Man can produce two types of light chains, designated $\varkappa$ and λ, and at least ten classes and subclasses of heavy chains. The human $\varkappa$ chain has been most thoroughly studied and serves as a general model for all immunoglobulin polypeptide chains[1]. The amino terminal half of the $\varkappa$ chain (residues 1–107) is designated the variable (V) region and presumably is responsible for encoding various antibody specificities because each variable region from $\varkappa$ chains ($V_\varkappa$) studied to date has a unique amino-acid sequence. The carboxy terminal half of this chain (residues 108–214) is designated the common (C) region and is invariant in all human $\varkappa$ chains apart from a single amino-acid interchange position 191 which is inherited in a Mendelian fashion[6–9]. Because of this Mendelian behaviour the $C_\varkappa$ region is probably encoded by a single structural gene with two allelic forms[10,11]. The $V_\varkappa$ regions in man seem to be encoded by multiple genes which can be associated with either allelic form of the $C_\varkappa$ gene[4,12–14]. Thus two genes probably encode each human $\varkappa$ chain (a $V_\varkappa$ gene and a $C_\varkappa$ gene) and these genes must be joined together at some level of protein synthesis to produce a single peptide chain. These generalizations, multiple V genes and a joining mechanism to unit separate V and C genes, seem to hold for the other immunoglobulin chains[15–18].

Structural studies on the immunoglobulins from species other than man have raised important questions about the evolution of immunoglobulin genes. For example, Doolittle reported that normal rabbit light chains, derived from a heterogeneous pool, had amino terminal residue alternatives which were different from their human counterparts[19]. Such unique amino-acids have been designated species specific residues. The question then arose how multiple genes could evolve in a given evolutionary line to generate species specific residues. Obviously a detailed examination of the extent and nature of species specific residues requires rabbit immunoglobulins of restricted heterogeneity. Such immunoglobulins are now available[20–24].

We report here amino terminal sequence studies on rabbit antibody light chains which demonstrate that the

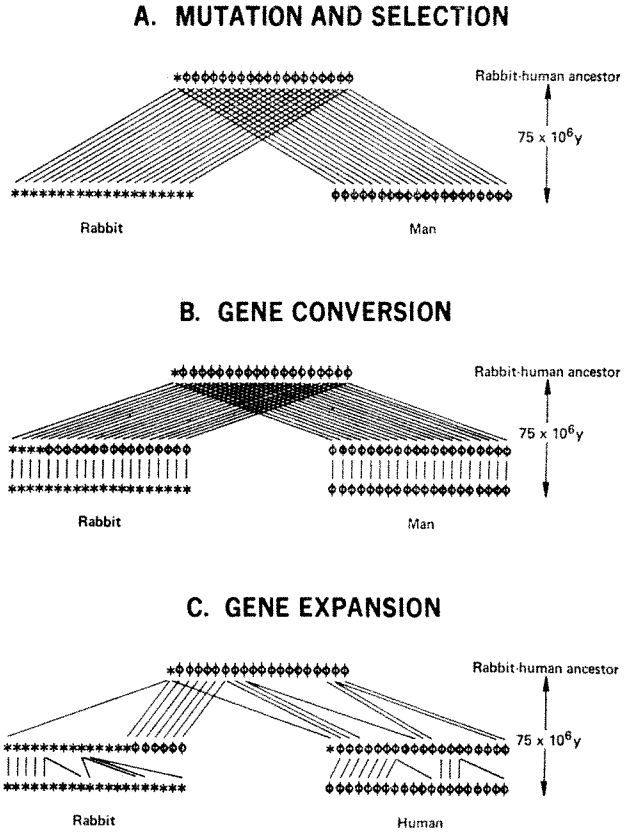

Fig. 1. Three models for the generation of species specific residues in a multigene system. Φ and * represent germ line genes differing at positions which are to become species specific. The genes present in the ancestor common to rabbit and man are represented at the top of each figure and the genes present in the contemporary individuals are at the bottom. These species diverged about seventy-five million years ago. *A*, Random mutation changes the rabbit Φ genes to * genes, and selection fixes these mutations. *B*, Gene conversion changes the neighbouring rabbit Φ genes to * genes by a process of non-homologous pairing and copy-repair[25]. *C*, The * gene is expanded by repeated duplication and integrated into the genome of the evolutionary line leading to contemporary rabbits. Later gene expansions of different individual members of the * gene family generate contemporary rabbit subgroups. The Φ gene is expanded in the human evolutionary line. Species specific residues occur because different genes are expanded in the two evolutionary lines. This diagram is not meant to indicate that there is an immediate compensatory loss of other V genes after the gene expansion. Rather, the genome probably expands and carries for a time the older functional genes as well as the newly expanded family.

V regions from these chains are encoded by multiple genes. This is suggested by their division into at least three subgroups. After appropriate alignment, the V regions from rabbit light chains are homologous to their human V_κ counterparts and presumably both were derived from a common ancestor. The existence of distinct species specific residues suggests that rapid gene expansion has occurred during the evolution of the immune system. We feel that this mechanism of rapid gene expansion must also be evoked to explain the evolution of other multigene loci such as the ribosomal system. Indeed the antibody system affords an excellent opportunity to study the general features of evolution in a multigene system. This will be discussed later.

Rabbits immunized with streptococcal vaccines may produce antibodies with restricted heterogeneity in concentrations which reach 30–50 mg/ml. of serum[20,23]. The nature of the antigen, the preparation, isolation and characterization of these antibodies and the separation of light and heavy chains have been described[25–28]. The amino-acid sequences of these light chains were determined using a Beckman model 890 protein sequencer[29] and the resulting phenylthiohydantoin derivatives were identified by gas chromatography[30] or by amino-acid analysis after hydrolysis to the free amino-acid[31,32].

Light Chain Sequences

N-terminal sequences for the light chains from eight antistreptococcal antibodies isolated from six rabbits are given in Fig. 1. Two antibody components of differing electrophoretic mobility were isolated from each of two rabbits, R24–36 and R24–61. Thus it became feasible to compare multiple antibodies of similar specificity from a single rabbit. The following points will be discussed: (1) the rabbit has three light chain V region subgroups; (2) the subgroups exist in normal rabbit light chains; (3) these subgroups are not alleles; and (4) the subgroups are apparently independent of light chain allotype.

The light chains of R27–11 and R24–36–I were examined as far as position 23 and 26 respectively. They are as homogeneous as control myeloma light chains over this portion of their sequence. These light chains, like Bence–Jones proteins, are distributed as a single component by polyacrylamide disc electrophoresis. The six other light chains had two principal residue alternatives at one or more positions. The disc electrophoresis of these light chains revealed two principal bands in each case. There is therefore an excellent correlation between the degree of heterogeneity of light chains as determined by amino-acid sequence analysis and by electrophoretic mobility[22]. On the basis of this limited sequence analysis, the restricted electrophoretic mobilities, as well as other characteristics[23], certain antistreptococcal responses seem to be primarily derived from a single antibody clone (R27–11), whereas others are derived from two (R26–90), three (R24–36), or even four (R24–61) principal clones. In each case, the heterogeneity is far less than is ordinarily present in the antibody responses to many other natural and synthetic antigens.

These light chain sequences can be aligned by homology with human κ chains (Table 1). For example, aligning the invariant Thr-Glu-Thr-Pro at positions 5–8 in both species shows that there are three discrete populations or subgroups of rabbit antibody light chains. These subgroups differ from one another in length at the amino terminus. The $V_{\kappa I}$ subgroup has an extra N-terminal residue, the $V_{\kappa III}$ subgroup has an N-terminal deletion, and the $V_{\kappa II}$ subgroup is the same size as its human counterpart. In addition to these size differences, it is also shown in Fig. 1 that certain amino-acid residues are correlated with the light chains of a given subgroup. For example, isoleucine is present at position 1 for $V_{\kappa III}$ proteins, aspartic acid at position 2 for $V_{\kappa I}$ proteins, and phenylalanine or isoleucine at position 2 for $V_{\kappa II}$ proteins. Other positions may also differentiate these subgroups (see position 13 in Table 1) but there are insufficient data to be certain.

These subgroups also seem to be present in normal rabbit light chains. Table 2 gives the residue alternatives present at the first eight positions of non-immune light chains from rabbit R14–43. Subgroup specific residues are present in these chains: $V_{\kappa III}$, position 1, Ile; $V_{\kappa II}$, position 2, Phe; $V_{\kappa I}$, position 2, Asp. Furthermore, the invariant Thr-Glu-Thr-Pro starts at three consecutive residues (4, 5, and 6) as would be expected for the three out of phase subgroups III, II, and I, respectively (see Table 2). At least 60% of the non-immune light chains in R14–43 probably fall into subgroups which are not selected by the streptococcal antigen as indicated in the legend to Table 2. Most of the non-immune chains are of the $V_{\kappa II}$ length. This can be seen at position 5 where

All rabbit chains are of the b4 allotype. All light chains are aligned to maximize their amino-acid sequence homology through the judicious use of gaps which are indicated [ ]. Certain of the rabbit light chains have two residues at a particular position (see text). ( ) indicates residues not identified. Two distinct antibody components were isolated from serum R24–36 and also from R24–61. These components had either intermediate (I) or slow (S) electrophoretic mobilities and were separated by agarose electrophoresis. The numbering is based on the human light chain length and is useful in making a comparison of proteins after they have been aligned. In discussing the sequence analysis of these subgroups in the text, the numbering will be different for $V_{\kappa I}$ and $V_{\kappa III}$ proteins. Sequence analysis starts at the amino terminus of each protein and accordingly the isoleucine in $V_{\kappa III}$ proteins is at position 1 and the aspartic acid in $V_{\kappa I}$ proteins is at position 2 (see Table 2). Group A: antibody to group A carbohydrate; group C: antibody to group C carbohydrate.

* Sequence present at the 70 per cent level.

approximately 70% of the molecules have the threonine expected of $V_{\varkappa II}$ proteins ($V_{\varkappa I}$ and $V_{\varkappa III}$ proteins have threonine at positions 6 and 4 respectively).

A somewhat arbitrary attempt has been made to construct subgroup sequences which can account for the residue alternatives observed in Table 2. The $V_{\varkappa I}$, $V_{\varkappa IIa}$ and $V_{\varkappa III}$ sequences correspond to the antibody sequences of Fig. 1. $V_{\varkappa IIb}$ and $V_{\varkappa IIc}$ are possible subgroup sequences not seen in this antibody population. Indeed, Jaton *et al.*[33] have reported an antipneumococcal antibody light chain with a sequence identical to $V_{\varkappa IIc}$. Thus the rabbit $V_{\varkappa}$ region as well as its human and mouse counterparts has multiple V region subgroups (4, 12, 14, 34). These rabbit subgroups differ, of course, from those in human and mouse light chains in that they have been derived from antibody molecules and not from myeloma proteins.

The existence of rabbit V region subgroups implies that there must be at least one gene for each subgroup. The rationale for this supposition has been thoroughly discussed elsewhere[4,5], and is summarized in Fig. 3. Furthermore, from published[35] and unpublished observations (L. H., H. L., K. E. and C. W. Todd), the light chains from thirteen normal rabbits have subgroup specific residues for each subgroup ($V_{\varkappa I}$-Asp at position 2, $V_{\varkappa IIc}$-Asp at position 1, and $V_{\varkappa III}$-Ile at position 1). Accordingly, every rabbit probably synthesizes proteins from each subgroup. The genes encoding these subgroups cannot be alleles; rather, they must be present in the germ line of each rabbit. Thus the V regions of rabbit $\varkappa$ light chains must be encoded by at least three germ line genes. (These subgroup specific residues are present in rabbits of differing light chain allotype: of the thirteen normal rabbits, nine were b4, three were b5, and one was b9. Thus the $V_{\varkappa}$ genes can be associated with any of the three light chain alleles studied.)

Table 2. AMINO TERMINAL RESIDUE ALTERNATIVES IN THE LIGHT CHAINS FROM NON-IMMUNE RABBIT R14-43 (b4 ALLOTYPE)

	Position 1	2	3	4	5	6	7	8
	Ala 78 Asp 19 Ile 3	Val 35 Asp 30 Tyr 20 Ala 5 Leu 5 Phe 5(Met)	Val 40 Ile 20 Asp 15 Leu 15(Thr) Glx 5	Val 50 Met 40 Leu 10	Thr* 70 Met 20 Glx 10	Glx Thr	Thr Glx (Pro)	Pro Ala Ser
$V_{\varkappa I}$	Ala	Asp	Val	Val	Met	Thr	Glx	Thr
$V_{\varkappa}$(a)	Ala	Phe	Glx	Met	Thr	Glx	Thr	Pro
(b)	Ala	Val	Ile	Val	Thr	Glx	Thr	Pro
(c)	Asp	Val	Val	Met	Thr	Glx	Thr	Pro
$V_{\varkappa III}$	Ile	Val	Met Val	Thr	Glx	Thr	Pro	Ser

The data are derived from amino-acid analysis of hydrolysed PTH derivatives and are expressed as the per cent of individual residues at positions 1–5. In subsequent positions only the principal residue alternatives are given. After position 1 all residue percentages are rounded off to the nearest 5%. Beneath the yield data are indicated the principal sequences which could account for the residue alternatives in the pool. The $V_{\varkappa IIb}$ and $V_{\varkappa IIc}$ sequences seem to comprise most of the normal light chain alternatives. The frequency of antibody subgroups can be estimated from the yields of subgroup specific residues (for example, $V_{\varkappa III}$-Ile at position 1, 3%; $V_{\varkappa I}$-Asp at position 2, 30%; and $V_{\varkappa II}$-Phe at position 2, 5%). ( ) indicates a minor residue (less than 5%) which is probably from the $V_{\varkappa III}$ subgroup.

* Threonine is destroyed by acid hydrolysis and was determined by gas chromatography.

Table 3. GENERATION OF RABBIT LIGHT CHAIN SUBGROUPS FROM A SINGLE "GENE"

	0	1	2	3	4	5	6
Prototype	Ala	Ala	Val	Val	Val	Thr	Glu
Subgroup	1	2	3	4	5	6	7
$V_{\varkappa I}$	Ala	[Asp]	Val	Val	[Met]	Thr	Glu
		1	2	3	4	5	6
$V_{\varkappa II}$	~~Ala~~	Ala	[Phe]	[Glu]	[Leu]	Thr	Glu
			1	2	3	4	5
$V_{\varkappa III}$	~~Ala~~	~~Ala~~	[Ile]	Val	[Met] Val	Thr	Glu

The prototype sequence is taken from the principal sequence alternatives present in normal light chains with an extra alanine at position 0 to generate the $V_{\varkappa I}$ proteins (see Table 2). To generate the three light chain subgroups from the prototype gene, certain residues must be deleted (residues crossed out) and others must be changed by mutation. Thus, a series of correlated events must occur to generate the three light chain subgroups. First, the N-terminal residue must be deleted for all proteins in the $V_{\varkappa II}$ subgroup and the N-terminal two residues deleted for all proteins in the $V_{\varkappa III}$ subgroup. Correlated with these deletions must be specific mutations at certain positions to generate the subgroup specific residues (for example, alanine to aspartic acid at position 2 and valine to methionine at position 5 in the $V_{\varkappa I}$ proteins, and so on) (see boxed residues). Thus, the generation of all rabbit light chains from a single gene seems unlikely. Rather, it is simpler to postulate that rabbits have at least three genes for light chain V regions, one gene for each subgroup.

Evolutionary Implications

The rabbit antibody light chains (b4 allotype) can readily be aligned by sequence homology against their human $\varkappa$ counterparts (Tables 1 and 4). Thus rabbit and human $V_{\varkappa}$ genes have descended from a common ancestor.

Although homologous, the $V_{\varkappa}$ regions of rabbit and man can readily be distinguished by certain species specific features. First, no set of human $V_{\varkappa}$ sequences corresponds to the rabbit $V_{\varkappa I}$ subgroup with an extra N-terminal residue, nor is there a set with the N-terminal residue deleted as in the rabbit $V_{\varkappa III}$ proteins. Second, several amino-acid positions in the light chains of rabbits are different from the same positions in the light chains of man (Table 4). The rabbit light chains in Figs. 1 and 4 have valine and glycine at positions 11 and 17, respectively, whereas most of their human and mouse counterparts have leucine and Asp/Glx, respectively, at these positions. Most normal light chains from these three species also have valine (rabbit) or leucine (man and mouse) at position 11 (L. H., M. Potter and C. W. Todd, unpublished observations).

The important new observation presented here is that species specific residues seem to be present on all light chain subgroups. If each $V_{\varkappa}$ subgroup is encoded by a different germ line gene, then multiple *V* genes in rabbit, mouse, and man must have evolved species specific residues. We shall examine models for the multigene evolution of species specificity shortly. First, it should be stressed that the number of $V_{\varkappa}$ subgroups in man (4 $V_{\varkappa}$), rabbit (3 $V_{\varkappa}$), and mouse (9 $V_{\varkappa}$) was determined from an analysis of relatively limited numbers of $\varkappa$ chains[4,34] and accordingly provides only a lower limit on the number of $V_{\varkappa}$ genes present in the germ line. Indeed, the immunoglobulin sequence data are consistent with a germ line hypothesis which suggests that a separate germ line encodes each distinct V region. Thus there may be as many as 20,000 antibody *V* genes[4]. There are, as we shall describe, precedents for such a multigene system. Moreover, these other multigene systems can also evolve in a species specific fashion.

Britten and his co-workers have demonstrated by DNA hybridization techniques that families of repeated DNA sequences are present in all higher organisms[36,37]. These repeated sequences comprise from 20 to 80 per cent of the total nuclear DNA. There are 50–2,000,000 related sequences per family. Some of the families are ancient (several hundred million years old) and individual members have diverged from one another significantly, while other families are recent and have diverged very little. RNA complementary to some repeated DNA sequences has been observed in every cell type studied. Thus certain of these repeated sequences must be transcribed and perform some function in eukarocytes.

Two of these multigene families have known functions. The tRNAs genes of higher organisms are probably present in multiple copies. For example, at least fifteen copies of each of the sixty tRNAs are present in *Drosophila*[38]. The number of ribosomal genes has been estimated to range from 100 to 400 in a haploid set of chromosomes in species as varied as yeast[39], *Drosophila*[40], frogs[41], pea seedlings[42], and man[43]. The ribosomal system has been studied in detail and has the following general properties: (1) the multiple ribosomal genes are all clustered at a single complex locus[44]; (2) the ribosomal genes of a single species are very similar[45] (little divergence has occurred); and (3) the ribosomal genes from

Table 4. A COMPARISON OF LIGHT CHAIN RESIDUE ALTERNATIVES IN MOUSE, MAN, AND RABBIT κ CHAINS AFTER ALIGNMENT TO MAXIMIZE SEQUENCES HOMOLOGY

The rabbit light chain alternatives are taken from the sequences presented here. The human κ chains are taken from ref. 4 and the mouse κ chains from ref. 34. The boxed residues are those which are unique to a single species (species specific residues) and present in three or more chains in that species. The alanine at positions 1 and 2 in rabbit chains is also boxed because it is seen at a significant level in normal rabbit light chains (see Table 2).
* These numbers indicate the number of myeloma or antibody light chains from which this information was obtained.

species widely separated on the phylogenetic tree can differ markedly in size[46], GC content[47], and base sequence[45]. Thus the ribosomal system is a clustered, multigene system with a specific set of functions which can evolve in a species specific fashion. In these characteristics the ribosomal system appears similar to the *V* genes of the immunoglobulin system. The ribosomal genes are different in that they appear to be much more highly conserved, as might be expected from their more limited range of functions.

Other multigene families, however, can diverge rapidly from one another, more in line with the rate of divergence of immunoglobulins. For example, Hennig and Walker have compared the DNA from sixteen members of two rodent families and conclude that even in closely related families, the banding profiles in CsCl and the reassociation rates of the DNA exhibit significant differences[48]. Thus individual families of genes must be able to change rapidly, such that, for example, those of the rat (*Rattus norvegicus*) can be readily distinguished from those of the mouse (*Mus musculus*). How is this species specificity generated ?

Two general mechanisms could generate species specificity in a multigene system. The co-evolution model suggests that multiple genes evolve in parallel in a given evolutionary line. Presumably different evolutionary lines would follow independent paths and accordingly species specificity will result (Fig. 1*A*, *B*). Three such examples will be considered. The gene expansion model postulates that in a given evolutionary line, a single gene is copied many times over, integrated into the genome and subsequent divergence generates a family of genes which deviate about an average sequence which corresponds to the gene originally expanded (Fig. 1*C*). If different genes are expanded in different evolutionary lines, species specificity will result.

Co-evolution: Mutation and Selection

Contemporary genes may have evolved in a direct linear fashion from their ancestral counterparts with species specificity being generated by random mutation and selection (see Fig. 1*A*). Such a model requires that identical (parallel) mutations occur in each gene and that these multiple mutations become fixed in the population. It is difficult to imagine selective pressures which could cause, for example, 500 ribosomal genes to evolve in parallel, particularly in view of the fact that frogs lacking half of their rRNA genes are quite viable[49]. This model seems very unlikely.

Co-evolution: Gene Conversion

Contemporary genes may be changed through a correction process involving other genes (Fig. 1*B*). Two such models have been proposed. Callan has suggested a master-slave model in which multiple gene copies (slaves) are corrected against a single copy (master) at each cell division[50]. Thus, all the slaves would appear to evolve as a single gene because they are all made identical to the single master gene at each cell division. This "effective" single gene system could explain species specificity in that a single gene in each species (master) directs the evolution of the entire multigene system. The master genes in rabbit and man might diverge just as have their single cytochrome genes and these divergences would be reflected in their respective families of slave genes. Obviously this mechanism cannot apply to antibody V regions as they are not all identical.

Gally and Edelman have proposed that favourable mutations could spread through a population of similar genes by "democractic gene conversion"[51,52]. In this model (Fig. 1*B*) any one of the multiple genes could undergo a favourable mutation and this mutation could spread to neighbouring genes. Again it is difficult to imagine what selective pressures could ensure that favourable mutations spread to each member of a large multigene family (for example, ribosomal genes). Democratic gene conversion postulates that gene conversion can occur among the antibody genes of a given V region subgroup, but not among genes of differing subgroups (otherwise it would be impossible to maintain distinct subgroups in a given species). Accordingly, this model fails to account for species specific residues which are present in multiple light chain subgroups (see positions 11 and 17 in the rabbit, Table 4). To explain these residues, the democratic gene conversion model would require independent mutation and selection for each species specific residue in each subgroup. This requirement is similar to that for the model in Fig. 1*A* and is accordingly unattractive. A more plausible explanation comes from a consideration of gene expansion.

Gene Expansion

Families of repeated nucleotide sequences may originate in rather sudden events of excessive replication of particular sequences. Such gene expansion has been designated saltatory replication[36] and is illustrated in Fig. 1*C*. A single gene in the rabbit–human ancestor may undergo one or more such expansions in the line that is to become the contemporary rabbit. Thus most of the contemporary rabbit antibody genes may have evolved from a single gene in the rabbit–human ancestor and likewise the contemporary human antibody genes may have evolved from one or a few different genes in this same ancestor (Fig. 1*C*). If the primitive rabbit gene differed at positions 11 and 17 from the primitive human gene, species specific residues would result. Later gene expansions could

generate the V region subgroups. The gene expansion model has three requirements. First, many gene copies must be made in a short period of time. Second, these gene copies must be integrated into the genome so they can be transmitted to progeny. Finally, the resulting gene family must determine or be associated with a favourable phenotype.

Strong support for sudden gene expansion (saltatory replication) comes from the mouse satellite DNA example[53]. The mouse (*Mus musculus*) genome has a satellite DNA which can be isolated from chromosomal DNA after shearing because of its unusual GC content. This satellite comprises 10% of the total DNA and represents approximately one million nearly identical copies of a nucleotide sequence about 300 residues in length. The guinea-pig (*Cavia porcellus*) also has a satellite DNA, but hybridization studies have demonstrated that these two satellite DNAs have little, if any, sequence homology[53]. Indeed, sequences homologous with the mouse satellite cannot be found in the genomes of guinea-pig (*Cavia porcellus*), rat (*Rattus norvegicus*), or the British wood mouse (*Apodemus sylvaticus*)[53]. Two conclusions can be drawn: first, mouse satellite DNA was generated after the divergence of mice and other rodents, and second, the mouse satellite gene copies are so similar they must have been generated recently (little divergence has occurred) and in a short period of time. This latter point suggests that more conventional genetic mechanisms of gene expansion such as non-homologous crossing over may occur too infrequently to explain the rapid generation of a million very similar gene copies. Because Hennig and Walker have found extensive divergences in the multigene families of rodents, rapid gene expansion must also occur in these other systems. Gene expansion therefore seems to be a general mechanism in the evolution of eukaryotes.

Is there a mechanism for eliminating multigene families which have become useless? It seems that there are controls on the levels of genomic DNA in higher creatures. For example, different mammalian species have amounts of nuclear DNA which vary by no more than 10%[54]. The same is true of reptiles and of birds[54]. Thus the net gain (or loss) from DNA expansion (and contraction) must be similar in various mammalian species. Although non-homologous recombination could eliminate large blocks of useless genes, obviously little is known about the specific mechanisms which regulate the mammalian genome size.

The nature of multigene systems has been studied at the nucleotide level primarily using unfractionated DNAs from different species. The antibody system affords the first opportunity to examine individual gene products and to characterize at the protein level the evolution of a multigene system. Further characterization of immunoglobulins from different species should therefore place additional constraints on the mechanism responsible for the evolution of multigene systems.

Specific antibodies with molecular uniformity, generated in certain rabbits in response to immunization with groups A and C streptococci, are especially useful proteins for studying rabbit immunoglobulin structure, genetics, and evolution. The work reported here indicates that rabbit light chains can be divided into at least three discrete subgroups which differ in size at their amino terminus. It seems likely that each subgroup is encoded by at least one germ line gene. These rabbit light chains (b4 allotype) are clearly of the $\varkappa$ type and have evolved species specific residues in the intervening 75 million years since man and rabbit diverged. A mechanism of gene expansion seems to be necessary to account for this species specificity. Indeed, gene expansion seems to be generally required of many systems in eukaryotes (for example, ribosomal genes and mouse satellite DNA), and may be a fundamental mechanism of gene evolution in higher organisms.

We thank Drs R. Asofsky, E. Davidson and M. Potter for suggestions and comments.

The work was supported by a grant from the US National Institutes of Health and by a grant-in-aid from the American Heart Association. It was also sponsored by the Commission on streptococcal and staphylococcal diseases of the Armed Forces Epidemiological Board, and was supported in part by the US Army Medical Research and Development Command.

Variability in the Lambda Light Chain Sequences of Mouse Antibody

by

Salk Institute for Biological Studies,
San Diego, California 92112

The simple pattern of variability in mouse lambda chains suggests that diversity is generated by somatic spontaneous mutation and by sequential selection by antigen of single step mutants.

THE ratio of $\varkappa$ to λ light chains in serum immunoglobulin varies considerably among species[1]. For example, in cow[1] the ratio is about 0·1; in man[2] the ratio is 2, and in the BALB/c mouse it is between 10 and 20 (unpublished data of M. G. W. and W. Geckeler). The same ratios are found in the plasmacytomas which arise in man and mouse (ref. 2 and unpublished data of M. G. W., M. C. and J. Hirst), showing that individual cells of the normal plasmacyte population are transformed, at random, to the neoplastic state.

The expression of the λ class within a species might be the consequence of its potential to contribute to immunoglobulin diversity relative to that of the $\varkappa$ class. In our hypothesis the serum ratio of $\varkappa/\lambda$ is an approximate reflexion of the germ-line variable gene ratio, $V_\varkappa/V_\lambda$. But if there is a special mechanism for generating diversity, it might be postulated to be defective in diversifying $\varkappa$ in cow, to operate equally well on both $\varkappa$ and λ in man and to be defective in diversifying λ in mouse, and so on. Sequence comparisons of the variable part of the λ chain in mouse could tell us if such considerations were relevant. Some preliminary data on the similarity of two λ chains produced by plasmacytomas of BALB/c mice[3,4] encouraged us to carry out this detailed study which shows that λ chains do vary in sequence but, as expected, the pattern of variability is much simpler than that found in humans.

Results of the sequence analysis are shown in Fig. 1 and the methods are described in the legend. Six of the ten λ chains seem to be identical as far as residue 113—the length of the variable region; two differ from these by one residue (one base change); one by two residues (two base changes); and one by three residues (four base changes). These differences can be seen in Fig. 2. We maintain that the overlapping group of six λ chains is coded for by a unique germ line gene which is varied in a step-wise fashion because each single point mutation is acted on by antigenic selection.

There are three regions of high variability in human light chains. These regions are probably involved in determining the contribution of the light chain to the antibody combining site[5]. These three "specificity" regions, it should be emphasized, cover only about 20 per cent of the length of the variable region. The striking finding is that all the amino-acid replacements that we observed fall precisely into these specificity regions (Fig. 2), providing strong evidence that antigenic selection acts principally on point mutations in these three regions. The fact that one λ chain (S178) differs by three amino-acids (four mutational steps) from the overlap sequence suggests that this selection is sequential on single step mutants because the four mutations are also all in the specificity regions.

This result allows another point to be made, namely that the four variant λ sequences are derived from one germ line gene coding for the six overlap sequences. We postulate, on the basis of a germ line model, that the mouse has a family of duplicated V_λ genes of which 60 per cent are identical and 40 per cent are varied. This family must have arisen recently by extensive duplication of one V_λ gene (the overlap) followed by divergence and antigenic selection. It might also be argued that the 60 : 40 ratio is a reflexion not of the germ line gene ratio but of strong antigenic selection, were it not for the fact that the overlap λ chains are associated with immunoglobulins with the different specificities of their heavy chains (unpublished results of M. G. C., M. W. and J. Hirst). The problem of the germ line model is to account for a selection for replacements in the specificity regions without accumulating any replacements elsewhere. From the totality of human sequences roughly 20 per cent of the residues are invariant, 20 per cent are in specificity regions and 60 per cent are neutral or modulating. Invariant residues are preserved because mutations affecting them destroy antibody structure. The replacements in specificity regions are strongly selected for by antigen. This accounts for their high frequency. Replacements occurring elsewhere, however, must be unselected or weakly selected because, in part, they are neutral or effective only in concert with previous mutations in specificity regions. These neutral or modulating mutations outside of the specificity regions should be at least twice as frequent as those in specificity regions. In a germ line model, in which there are about 100 V_λ genes, the four mutations leading the three amino-acid replacements in the specificity regions of the S178 λ-chain would have had to be selected without any one of an expected eight or more neutral mutations occurring elsewhere in the postulated S178 germ line gene coding for the V region. This is unlikely. In a somatic model with sequential selection on single step mutants from one germ line V_λ gene, neutral mutations would be seen only very rarely in the initial stages of selection. This is why, for example, the constant region coded for by one germ line gene seems to be constant. Consequently, we take the overlap sequences to be coded for by a single V_λ germ line gene and only a somatic model will be considered from now on.

Our findings merit a comparison of the diversities within human and mouse V subgroups and a discussion of the distribution of the total subgroups between $\varkappa$ and λ in these two species. Human light chains within a subgroup show an average of thirteen amino-acid replacements in any two proteins compared with one in mouse λ. On purely *a priori* grounds a greater degree of diversity would be expected for humans than for inbred BALB/c mice. Aside from the problem of polymorphism, the human light chains are derived from individuals with a history of approximately 50 years of somatic diversification whereas the mouse light chains are derived from individuals of 0·5 years of somatic diversification. If we could study the amino-acid replacements in human light chains during the initial stages of diversification, the same

Fig. 1. Partial sequence of mouse λ chains. Two of the light chains in this comparison are produced by tumours donated by Drs M. Potter and K. R. McIntire, NIH, and designated RPC-20, HOPC-1, and MOPC-104E. Tumour XP8 is a variant of tumour MOPC-104E (ref. 8). S104, S178, J698, H2020, H2061, J558 and S176 are λ chain producing tumours induced in our laboratory. Tumours J698, H2020, H2061 and J558 produce myeloma proteins of the γA type. These proteins were isolated from the sera of tumour-bearing mice[9], and the light chains were isolated from these proteins[10]. RPC-20 and S178 secrete exclusively λ chain which was isolated from the urine of female BALB/c mice bearing these tumours[9]. Tumours S104, HOPC-1 and XP8 produce myeloma proteins of the γA, γG2a, and γM classes respectively as well as urinary λ chains. In these cases light chain was isolated from the urine. The purified light chains were aminoethylated[11] and oxidized with performic acid[12]. The tryptic peptides from the first 113 residues were isolated and further digested with either thermolysin or chymotrypsin. These peptides were separated and analysed as previously described[13] with the modification that peptides were eluted and hydrolysed in 6 M HCl in 4 per cent thioglycolic acid[14]. Certain of the peptides from each protein resulting from these digestions are shown. For certain of these peptides part of the sequence of amino-acids has been determined by the subtractive Edman procedure[15] after elution from the fingerprint paper with 50 per cent pyridine. The positions of these peptides in the sequence were determined by their homology with the peptides of the S178 protein for which the order of peptides has been determined, and the amino-acids in each peptide were aligned by homology with what we believe to be the sequence of the S178 protein, with the exception of the sequence between residues 3–10 and 41–43 (I. C., and M. G. W., manuscript in preparation). The sequence 3–10 is aligned according to ref. 4; 41–43 is still in doubt. Portions for which the exact sequence has been determined by the subtractive Edman procedure or is inferred from the known action of the enzymes used for digestion of the S-aminoethylated protein are placed outside the brackets. The position of the tryptic peptide comprising the first twenty-three residues of these proteins was identical in fingerprints of tryptic digests of performic acid oxidized protein. Because this peptide did not react with the ninhydrin reagent, it was detected using an arginine specific stain[16]. The peptide could be located on one dimensional electrophoresis by staining guide strips for arginine containing peptides[16]. The peptide was eluted from the unstained portion of the paper and analysed for amino-acid composition or digested with thermolysin. The peptides resulting from thermolysin digestion were separated by one dimensional electrophoresis and guide strips were stained with ninhydrin and by chlorination[17]. One ninhydrin-negative peptide, detected by chlorination, had the composition Glu-Ala. It was assumed that this peptide represented the first two residues of the λ chains, and that the first residue of the λ chains was pyrrolidone carboxylic acid. The compositions of the peptides were determined after acid hydrolysis, so that it is not possible to distinguish between glutamine and glutamic acid or asparagine and aspartic acid. But because all the peptides had identical electrophoretic mobilities it is unlikely that there are differences involving these amino-acids. It is inferred that the residue at position 25 and 52 in the S178 protein and at 25 in the S176 protein is asparagine rather than aspartic acid, for the electrophoretic mobility of the peptides containing this residue is identical to the corresponding peptides from other proteins in which either a glycine or serine replacement occurs.

characteristically simple pattern seen for mice should emerge. But because the available human light chains are the products of genes which have undergone many sequential steps of somatic antigenic selection, the simple pattern is camouflaged. It can be revealed, however, by statistical analyses of the kind illustrated in Fig. 2 (ref. 5). Extensive sequential selection leads eventually to a steady state of diversification in which the rate at which new mutations creating additional specificities are fixed by antigenic selection equals the rate at which already acquired specificities are lost. This steady state population can accumulate both neutral and modulating replacements outside the critical regions. The steady state in humans seems to occur when the average number of amino-acid differences between two random chains in a subgroup is about thirteen. This implies an average of six mutational steps from the germ line gene. The BALB/c mouse is far from this steady state level although in principle, given a long enough life span during which antigenic selection could act, it too would approach this value of six. At the extreme we have seen that BALB/c mice can express variant λ chains such as S178 which are four mutational steps away from the germ-line gene, a value close to the average for humans. We conclude that the rate at which diversity is being generated in mouse λ is not particularly low.

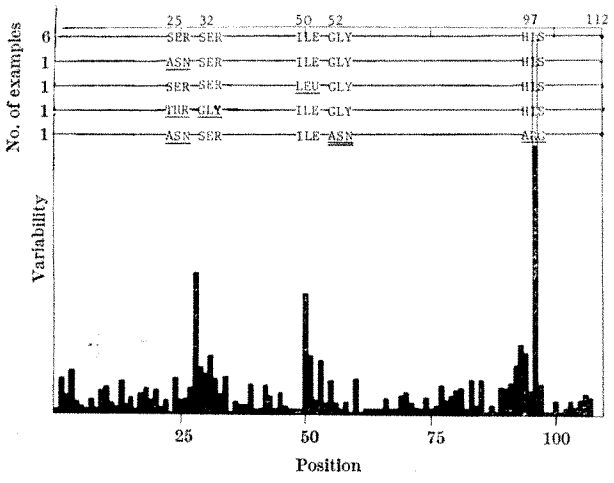

Fig. 2. Diagram of mouse λ sequences superimposed on a plot of the extent of variability versus position in the variable region sequences of human light chains, κ and λ. The portions of the mouse λ proteins in which no differences could be detected are indicated by a line. The positions at which differences were found are indicated by the residues involved. The underlining indicates the number of base changes needed to get the replacement. The plot is taken from ref. 5.

Now we shall look at the distribution of V subgroups in man and mouse. In man four or five V_κ and five V_λ subgroups are known[6] so that the ratio of germ line genes for V_κ/V_λ is one. In the BALB/c mouse there are (by our interpretation of the data) about twenty V_κ subgroups[7]. The V_κ/V_λ ratio is therefore twenty, for only one subgroup is found to be associated with the BALB/c λ chain which is defined by its C terminal peptide . . . Ala-Asp-Cys-Ser (ref. 3 and unpublished data of M. G. W. and W. Geckeler).

It seems likely to us that the wide range in serum ratios of κ/λ in different species is a reflexion of the germ line gene ratios V_κ/V_λ. Were selection by the random population of antigens to act equally well on all V subgroup genes then the serum ratio of κ/λ in man should be one and in mouse twenty, a value close to that found. If the κ/λ ratios in serum were explicable in terms of a special mechanism operating with differential effectiveness on V_κ and V_λ genes, in man V_κ and V_λ would be diversified with equal effectiveness whereas in mouse only V_κ would be diversified. The variation that we have observed in mouse V_λ would be due to spontaneous mutation. In the mouse the germ line V gene ratio reflects the serum ratio of κ/λ, so we conclude that the postulated special mechanism is no more effective than spontaneous mutation in generating diversity. Consequently, postulates of special mechanism for diversification by hypermutation hyperrecombination are gratuitous. Clearly, it is more reasonable to suppose that the total of about ten to twenty V subgroups seen for mouse or human light chains is the minimum needed to prime the process of diversification rapidly. This suggests that the variation within a mouse κ chain subgroup will also follow a pattern of variability as simple as that found in mouse λ chains.

Let us assume that the distribution of mutations which are fixed by antigenic selection in λ chains is random and follows a Poisson distribution. From the fact that six out of ten λ chains are the expression of a germ line gene, we can calculate that there is an average of 0·5 mutation per chain. The distribution, therefore, is 60 per cent with no mutations, 30 per cent with one mutation, 8 per cent with two mutations, 1 per cent with three mutations and 0·2 per cent with four mutations. Because a mutation that is fixed by antigenic selection implies an amino-acid replacement, 40 per cent of the total λ chains will be variant of which 75 per cent (30/40) will have only one replacement. Single replacements therefore account for most of the diversity. Because these antigenically selected single replacements are limited to the specificity regions, there will be in a mouse only about fifty different functional λ chains. If every germ line V gene for the light and heavy chain is diversified to the same extent and if there are a total of twenty germ line V genes for light and five for heavy chain then the 0·5 year old mouse (the age at which plasmacytomas were obtained) can make 10^5 different antibodies solely as a consequence of single mutations. If the rate of increase in diversity were linear (the crudest assumption), then a 1 week old mouse could express 5,000 different antibodies. This would tax the immunologist's ability to detect any missing specificities.

Consequently, our interpretation of these data is that the six identical λ chains are coded by one germ line V_λ gene which is diversified somatically by spontaneous mutation to yield the four variants. The first single step mutants selected for by antigen are those which occur in the three critical regions responsible for the specificity. The process of selection is sequential on each additional mutation conferring a new specificity.

Reactivity of Inbred Mouse Sera with Antisera to the Variable Region of Light Chains

by
A. RUFFILLI*
C. BAGLIONI

Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139

The presence of common antigenic determinants in a panel of human and mouse Bence–Jones proteins and a human myeloma protein has facilitated a study of the genetic control of immunoglobulin synthesis in mice.

LIGHT chains of immunoglobulins have a variable and a common region, corresponding respectively to the N-terminal and C-terminal half of the amino-acid sequence[1]. Subdivision of light chains into K type and L type is based on the sequence of the common region[1]. One structural gene codes for the common region of K type proteins in man, whereas two genes code for the common region of L type proteins[2–4]. The number of genes that code for the variable regions of light chains in the genome of each individual has not yet been determined.

In human Bence–Jones proteins there is a relatively small number of basic sequences for the variable region of light chains[5,6]. The other known sequences can be derived from the basic sequences by substitution of a few amino-acids[5,6]. Light chains related to the same basic sequence are thought to belong to a subgroup, three of which have so far been identified for K type proteins and four or possibly five for L type proteins[1]. Subgroups have also been identified for K type mouse Bence–Jones proteins[7,8].

The genetic control of the structure of light chains has not been explained. It is not known whether there is a single structural gene, coding for each basic sequence and subject to somatic variability generating processes, or whether there are as many structural genes as there are variable sequences.

We report here a study on the genetic control of the variable region of light chains in inbred mouse strains. Because it is impossible to isolate single molecular species from the immunoglobulins of an individual, unless the individual has been immunized in such a way as to produce a monoclonal antibody, a method was devised to identify and estimate antigenic determinants of immunoglobulins by means of serological reactions carried out with unfractionated serum. The method used to estimate an antigenic determinant was the inhibition of precipitation of an iodinated antigen[9]. For example, in the precipitin reaction defining determinant *a* we used an antiserum prepared against the fragment[10] of human Bence–Jones protein 27 (BJ 27), which corresponds to the N-terminal half[11]. (Human Bence–Jones proteins and protein fragments were obtained from sources reported in ref. 10.) To increase its specificity, we absorbed the antiserum (anti-BJ 27f) with a different Bence–Jones protein (BJ 79) conjugated to bromoacetyl-cellulose[12] and tested sera or immunoglobulins for inhibition of the precipitin reaction anti-BJ 27f/[^{125}I]BJ 27, as described in detail previously[9]. Antisera prepared in different ways were used to define two other antigenic determinants of light chains, called *b* and *c*[9]. Details of the experimental conditions are given in the legend to Table 1.

The presence of antigenic determinants *a*, *b* and *c* in a panel of human and mouse Bence–Jones proteins and one mouse myeloma protein has been investigated[9]. Some proteins inhibited the precipitin reactions, whereas others of the same type did not. This was taken as an indication that the antigenic determinants were present in the variable region of cross-reactive human and mouse light chains (see ref. 9). These antigenic determinants were not species-specific but were present in the light chains of man, mice, rat, pig, horse, sheep and cattle; they were not present in the heavy chains of these species nor in chicken immunoglobulins[9].

Table 1. DISTRIBUTION OF DETERMINANTS *a*, *b* AND *c* IN A GROUP OF HUMAN AND MOUSE BENCE–JONES PROTEINS AND IN A MOUSE MYELOMA IMMUNOGLOBULIN

	Determinants			
Human Bence–Jones proteins	*a*	*b*	*c*	Type
BJ 27	+	+	−	L
BJ 27f	+	+	−	L
BJ 79	−	+	−	L
BJ 99	−	+	+	L
BJ 10	−	+	−	L
BJ 1	+	+	+	L
BJ 98	−	+	−	L
Mouse Bence–Jones proteins				
MOPC 41 A	+	+	+	K
MOPC 46 B	−	−	−	K
MOPC 29 A	−	−	−	K
MOPC 197 A	−	−	−	K
MOPC 30 A	−	−	−	K
RPC 5 (IgG)	+	+	+	K
MOPC 20	−	−	−	L

The antigenic determinants *a*, *b* and *c* are defined by precipitin reactions of antisera directed against the variable region of human L type Bence–Jones proteins with BJ 27, BJ 79 and BJ 99 respectively. The preparation of the antisera and their fractionation have been described[9]. The antisera were fractionated so as to render them specific for a single antigenic determinant (or a group of determinants present together on the same protein). Ten μg/ml. of each iodinated Bence–Jones protein used as antigen were incubated for 1 h at 37° C with the corresponding antiserum at equivalence in the presence of 5 to 100 μg/ml. of proteins tested as inhibitors. The equivalence zone was determined for each precipitin reaction as previously described[9]. The incubation mixtures were then placed for 2 days at 4° C to ensure maximal precipitation and then filtered on Whatman GF glass filters and counted as previously described[9]. The table summarizes the results of inhibition of precipitation reactions: + indicates an inhibition of more than 80%; −, an inhibition of less than 20%. Controls were run by substituting each antiserum with serum of a non-immunized rabbit.

To study the genetic control of variable regions of light chains, we have analysed pooled sera of inbred mice and sera obtained from individual mice. Pooled sera and mice were obtained from the Jackson Laboratory, Bar Harbor, Maine. To establish that determinant *a* could be identified in serum immunoglobulins and that a reliable estimate of the fraction of light chains carrying determinant *a* could be obtained, the following preliminary experiments were carried out. Mouse Bence–Jones protein[10] MOPC 41, IgG myeloma protein MOPC 5, pooled IgG (purchased from Pentex), light chains prepared from pooled IgG[13], and pooled serum of non-inbred Swiss mice were used as inhibitors of the precipitin reaction defining determinant *a*. It was found that the cross-reacting mouse Bence–Jones protein MOPC 41 competed with BJ 27 with similar affinity for the antiserum. From the inhibition curves reproduced in Fig. 1 it was

* Present address: International Laboratory of Genetics and Biophysics, Naples.

calculated that 5·5 μg of MOPC 41 gave 50% inhibition of precipitation in the presence of 5 μg of [^{125}I]BJ 27.

Light chains in IgG molecules inhibited the precipitin reaction with approximately the same efficiency as free light chains; 14 μg of the cross-reacting myeloma immunoglobulin RPC 5 gave 50% inhibition of the precipitin reaction defining determinant *a*. Similarly the amount of pooled light chains and pooled IgG required to obtain 50% inhibition of the precipitin reaction were determined to be respectively 62 and 220 μg. In these reactions the amount of [^{125}I]BJ 27 present in the incubation mixture was 10 μg (see legend to Table 1), so the calculated fraction of light chains carrying determinant *a* represented approximately 14% of the pooled light chains. An independent estimate of the amount of light chains carrying determinant *a* was obtained by analysing mouse serum in the same way. The pooled serum of non-inbred Swiss mice used in this experiment contained 6 mg/ml. of immunoglobulin. From the inhibition curve it was calculated that 36 μl. of this serum, containing 216 μg of immunoglobulin, were required for 50% inhibition of the precipitin reaction. This was very close to the amount of pooled IgG required for 50% inhibition, 220 μg.

The results of the analysis of sera of inbred mice are reported in Table 2. The number of μl. of serum required to obtain a 50% inhibition of the precipitin reaction identifying determinant *a* were calculated from the inhibition curves obtained in three independent experiments; the values obtained were within a ±10% range. Very similar values were obtained for eighteen of the nineteen sera examined. The amount of serum of ST/bJ mice required for 50% inhibition was about seven times lower than that of other mice, indicating that a much larger fraction of the light chains of ST/bJ mice carried determinant *a*.

Differences in the inhibitory titre of serum of mouse strains could be the result of different levels of serum immunoglobulins. To test this, the immunoglobulin level in sera of inbred mouse strains was determined by measuring the inhibition of precipitation of [^{125}I]IgG with anti-mouse IgG. Inhibition curves were obtained for each serum as already described[9] and the amount of serum required for 50% inhibition of the precipitin reaction was calculated (Table 2): the differences in IgG level were relatively small. Taking into account these differences, it was calculated that for fifteen of the sixteen strains examined, the fraction of light chains carrying determinant *a* varied between 11% (SWR/J) and 15% (BALB/cJ). In ST/bJ mice this fraction of light chains represented 80% of the total light chains.

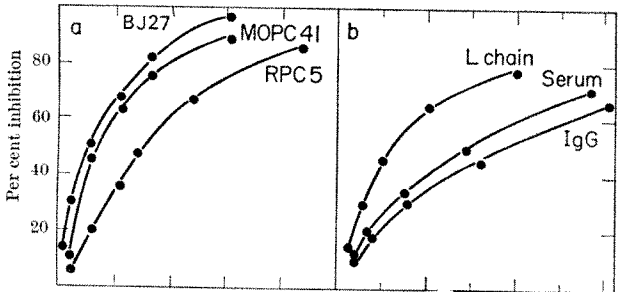

Fig. 1. Inhibition curves of the precipitin reaction anti-BJ 27f/[^{125}I] BJ 27. (This precipitin reaction defines determinant *a*).

a, Inhibition curves of BJ 27, a human Bence–Jones protein, of MOPC 41, a mouse Bence–Jones protein, and of RFC 5, a mouse IgG myeloma protein[10]. The conditions of the experiment are as described in the legend to Table 1. *b*, Inhibition curves of mouse pooled IgG (Pentex), mouse pooled light chains, and mouse pooled serum. The conditions of the experiment are as described, but antigen was used at a concentration of 200 μg/ml. and the antiserum was undiluted. The concentration of immunoglobulins used as inhibitors is indicated; for the experiment in which serum was used, the number of μg of immunoglobulin present in serum are indicated.

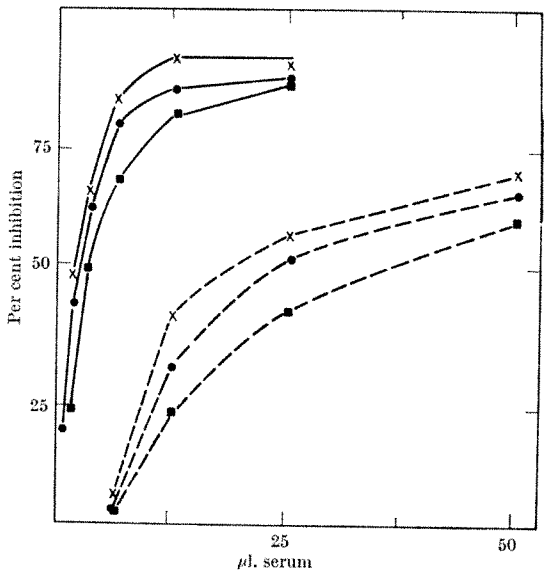

Fig. 2. Inhibition curves of the precipitin reactions defining determinant *a*. Pooled sera of ST/bJ and C57BL/6J mice were used as inhibitors of these reactions. The conditions of the experiment are those described in Table 1. The antisera were used undiluted. The concentrations of the iodinated antigens were; for the reaction defining determinant *a* 100 μg/ml.; for the reaction defining determinant *b* 150 μg/ml., and for the reaction defining determinant *c* 200 μg/ml. ———, ST/bJ serum; - - - -, C57BL/6J serum; ×, inhibition curves of the reaction defining determinant *a*; ●, *b*; and ■, *c*.

The sera of twenty-one C57BL/6J mice and of seven ST/bJ mice were individually examined for inhibition of the precipitin reaction defining determinant *a*. The number of μl. of serum required for 50% inhibition was calculated as described; they were found to range between 16 and 27 for C57BL/6J mice (average value 22·61) and between 1·4 and 2·5 for ST/bJ mice (average value 2·25). Thus all the sera examined contained a fraction of immunoglobulins carrying determinant *a* and this fraction is remarkably constant in individuals of the same inbred strain.

We have previously shown that determinants *a*, *b* and *c* are present together in the mouse Bence–Jones

Table 2. DISTRIBUTION OF ANTIGENIC DETERMINANT *a* AND QUANTITATIVE ESTIMATION OF IgG IN SERA OF INBRED MOUSE STRAINS

Strain	μl. of serum required for 50% inhibition of precipitin reaction	
	Determinant *a*	IgG

SM/J	24	29
SWR/J	19	20
ST/bJ	2, 2	15

The data were obtained from inhibition of precipitation of the reactions anti-BJ 27f/[^{125}I]BJ 27 and anti-Ig$_{mouse}$/[^{125}I]IgG$_{mouse}$. Mouse sera of the strains listed were used as inhibitors of these reactions. [^{125}I]BJ 27 was used at a concentration of 100 μg/ml., and dissolved in borate–saline buffer (*p*H 8·4). 50 μl. of this solution were added to 50 μl. of anti-BJ 27f diluted 1 : 2. These concentrations were found to correspond to equivalence for the precipitin reaction. After incubation for 1 h at 37° C 50 μl. of mouse serum diluted at different concentrations with borate–saline buffer were added and the incubation at 37° C was continued for one additional hour. The samples were then placed at 4° C for 24 h and filtered afterwards through Whatman GF/A filters[9]. The radioactivity retained on filters was then determined as previously described[9]. Inhibition curves were drawn for each experiment and the amount of serum required to obtain 50% inhibition of precipitation determined from these curves. The values reported are the averages of three independent determinations. The values obtained were in all cases within a ±10% range. [^{125}I]IgG$_{mouse}$ was used at a concentration of 2·5 mg/ml. and dissolved in borate–saline buffer (*p*H 8·4). 50 μl. of this solution were added to 50 μl. of undiluted anti-IgG$_{mouse}$ obtained from Pentex. The inhibition reaction was performed as described.

proteins or myeloma proteins examined and are also very frequently present together in the same molecules of pooled light chains[9]. The reasons for this behaviour of these antigenic determinants are not clear, but we have suggested that they are in some way related[9]. To confirm the results obtained with determinant *a*, pooled sera of ST/bJ and C57BL/6J mice were examined for inhibition of the precipitin reactions defining determinants *b* and *c*. The antisera and antigens used in these precipitin reactions have been described[9]. The inhibition curves obtained are shown in Fig. 2. The amount of serum required for 50% inhibition of the precipitin reactions defining determinants *b* and *c* were 2·3 and 3·3 μl. respectively for ST/bJ serum and 25 and 38 μl. respectively for C57BL/6J serum. This confirmed that these antigenic determinants are present in proportionally similar amounts in different sera and are thus presumably present in the same light chain molecules.

Our findings indicate that the relative amount of light chains carrying determinant *a* is remarkably constant in different inbred strains of mice. Only in ST/bJ mice is the fraction of light chains carrying determinant *a* much greater than in the other strains: this is difficult to interpret without further information on the structure of light chains in ST/bJ and in the other mouse strains.

It seems likely, however, that the relative proportion of light chains carrying determinant *a* is under genetic control. Crosses of ST/bJ mice with other inbred mice and a study of the offspring might help to establish this point. We hope that it will be possible in this way to gain information which will support or disprove some of the theories that have been suggested to explain the variability in amino-acid sequence of antibody peptide chains. Among the mechanisms that have been suggested are recombination between a small number of genes coding for the variable region[14] and somatic hypermutation of a small number of structural genes[15]. Both mechanisms presuppose the existence of a small number of genes only, coding for the variable region of light chains; it may well be possible that by studying inbred mouse strains we could establish the existence and learn about the inheritance of these hypothetical genes.

This research has been supported by an NIH grant. We thank Drs M. Potter and K. R. McIntire (NIH) and Dr P. Knopf (Salk Institute) for providing mouse Bence–Jones proteins and myeloma immunoglobulins.

DNA Polymerase II

by
ROLF KNIPPERS
Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, Tübingen

A membrane associated DNA polymerizing enzyme has been solubilized, partially isolated and characterized.

In a cell free extract of *Escherichia coli pol A*⁻ (DNA polymerase negative) mutant cells[1] most of the residual DNA synthesizing activity is associated with a fast sedimenting cellular component, most probably the cell membrane[2]. This complex can perform several functions characteristic of DNA replication and produces new DNA semiconservatively at a polymerization rate close to that observed for DNA replication *in vivo*[3]. A bothersome feature of the membrane system, however, is its brief active period; DNA is replicated for only a few minutes. I shall describe briefly in this article a procedure to solubilize and characterize an enzyme associated with this system. This released enzyme will be called DNA polymerase II, and the enzyme described by A. Kornberg[4], DNA polymerase I.

In a series of pilot experiments I found that non-ionic detergents solubilize an active deoxynucleoside triphosphate polymerizing activity from the fast sedimenting cellular structure. Fig. 1*a* shows that the membrane structure identified by the radioactive label in its lipid component (extractable by chloroform–ether) bands as a rather diffuse peak in the sucrose gradient and carries nearly all the DNA synthesizing activity. After treatment with the detergent most of the DNA synthesizing activity is found floating on top of the gradient, probably in a molecular form too small to sediment far during the relatively short centrifugation period. This and similar experiments encouraged me to try the isolation of the solubilized incorporating activity. Table 1 shows the procedure used. Other detergents like sodium deoxycholate were also successfully used in removing an active DNA synthesizing activity from the membrane; a prolonged incubation in 0·01 M EDTA was less effective.

Properties of the Solubilized Enzyme

The molecular weight of DNA polymerase II was estimated to be in the range of 60,000—90,000[7] by gel filtration on 'Sephadex G-200'; this shows that the enzyme is indeed released from larger cellular structural components. The optimal conditions for enzyme activity are *p*H 7·6 (*cf.* the membrane system's *p*H optimum is *p*H 7·0), 0·008 M $MgSO_4$, 0·05 M KCl. The incorporation of 3H-TTP into acid precipitable deoxyribonuclease sensitive material (Fig. 2) proceeds linearly for at least 90 min in marked contrast to the enzyme *in situ* where deoxynucleoside triphosphates are polymerized for only a few minutes.

Table 2 summarizes further properties of the enzyme. Because an excess of unlabelled TTP rather than TDP (or TMP) depresses incorporation of radioactive ^{3}H-TTP

into acid precipitable material, I conclude that the triphosphates are the precursors for the polynucleotide synthesized. The enzyme is strongly inhibited by mercuri-compounds, like the intact membrane system but unlike DNA polymerase I. The enzyme activity is resistant to preincubation with an antiserum against DNA polymerase (prepared by Dr T. Jovin and made available to me by Dr H. Schaller); the activity of DNA polymerase I, incubated under the same conditions with the antiserum, decreases to 10 per cent of a control value.

Table 3 shows that the activity depends on an external DNA primer (unlike the membrane system which seems to use exclusively the cell DNA attached to it). Best primers are ultrasonically sheared DNA pieces with molecular weights around 1–2 million. Fragments of *E. coli* DNA, calf thymus DNA and T7-DNA, when offered in equal amounts, possess the same priming activity.

Single stranded DNA, extracted from phages fd or φX 174, or produced by heat denaturation of *E. coli* and calf thymus DNA fragments, are not accepted as primers for DNA polymerase II. Supercoiled φX-RF (the double stranded form of circular φX DNA) also does not prime the DNA polymerase II reaction; introduction of several endonucleolytic nicks (by pancreatic deoxyribonuclease) converted the φX-RF into a good primer for the DNA polymerase I but not for the DNA polymerase II. High molecular weight *E. coli* DNA can be converted into an effective primer of the DNA polymerase II by pretreatment with exonuclease III[8], an enzyme which attacks double stranded DNA at its 3′-ends. The ^{3}H-labelled DNA synthesized on such a primer DNA is double stranded as judged from its buoyant density in CsCl equilibrium gradients and its inability to adsorb to nitrocellulose filters at high ionic strength. Such a pretreated DNA

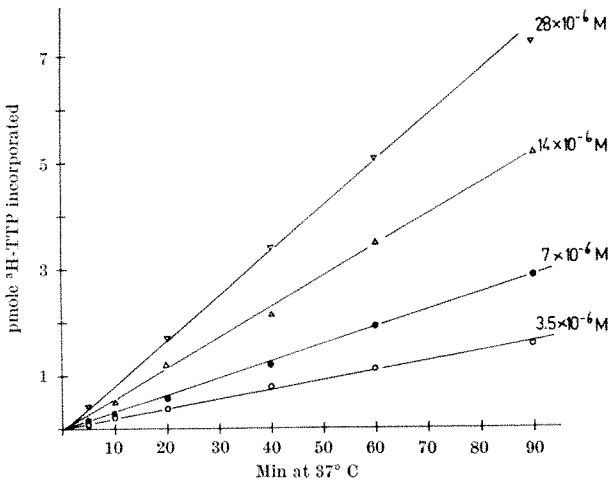

Fig. 2. Kinetics of incorporation. Reaction mixtures: the buffer was 0·08 M KCl–0·05 M Tris-HCl (*p*H 7·6)–0·007 M $MgCl_2$–0·005 M mercapto-ethanol; 12 μg sheared calf thymus DNA; about 0·9 μg of the enzyme preparation; the four dNTPs in concentrations given on the graph; specific activity of ^{3}H-TTP is 10 μCi/μmole. The final volume was 0·7 ml. Samples (0·1 ml.) were withdrawn from the reaction mixture and diluted into cold 0·9 ml. 0·01 M EDTA. The DNA was then precipitated with trichloroacetic acid on 'Millipore' filters and radioactivity was counted.

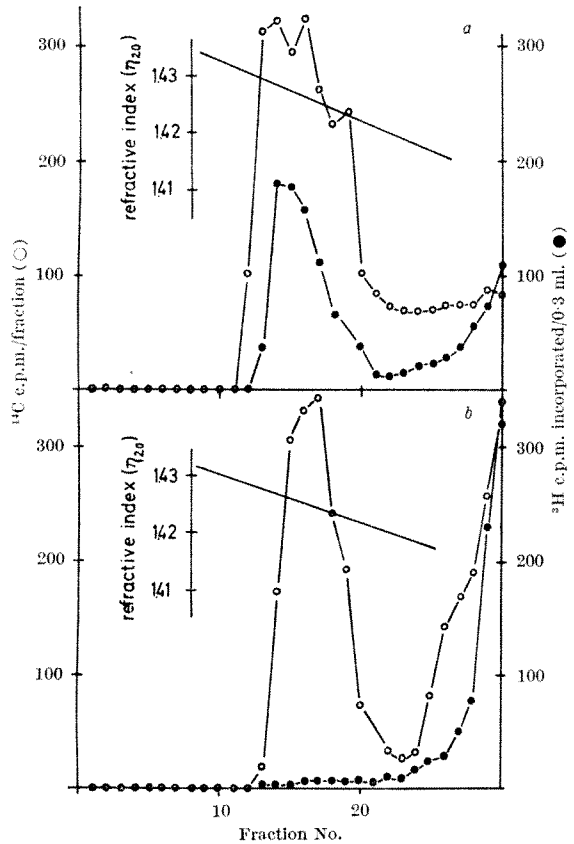

Fig. 1. Effect of detergents on *E. coli* membrane preparations. An oleic acid requiring derivative of the strain *E. coli* H 560 (DNA polymerase negative, endonuclease I negative; constructed by Dr Hoffmann-Berling by a cross between the Cairns–de Lucia mutant and an endonuclease I⁻-donor strain) was grown in a synthetic medium[5] supplemented with 0·1 μg/ml. ^{14}C-oleic acid (0·5 μCi/μmole). The harvested cells were treated with lysozyme in a 20 per cent sucrose solution buffered by 0·05 M MOPS (morpholinopropane sulphonic acid, adjusted to *p*H 7·2)–0·005 M EGTA and lysed with the nonionic detergent 'Brij 58'[9]. The resulting viscous cell lysate was briefly sonicated and the membrane fraction prepared by sedimentation through a sucrose gradient as described[2], treated for 2–3 s with a sonifier and dialysed. One part (*b*) was treated with 'Triton X-100' (an anionic detergent: alkylphenoxy-polyethoxyethanol which is currently used in many laboratories to solubilize bound proteins[14,15]) at an approximate detergent : protein ratio of 0·5; the other part served as control. Both lysates were then centrifuged through 26 ml. preformed linear 60–40 per cent sucrose gradients buffered in 0·1 M Tris-HCl (*p*H 7·6)–0·005 M mercaptoethanol–20 per cent glycerol. The 'SW 27' rotor of the Spinco centrifuge was used for 16 h at 25,000 r.p.m. and 6° C. 0·3 ml. samples were removed from each fraction, supplemented with $MgSO_4$ (final concentration 0·005 M), with the four deoxynucleoside triphosphates (2×10^{-5} M each; ^{3}H-TTP 50 μCi/μmole) and 4 μg ultrasonically sheared calf thymus DNA. Incubation was at 37° C for 30 min. The refractive index indicates the density increment in the gradients. *a*, Untreated control sample; (*b*) 'Triton X-100' treated membrane preparation.

Table 1. THE ISOLATION PROCEDURE

	Vol. (ml.)	Protein conc. (mg/ml.)	Enzyme units/ml.	Specific activity (units/mg protein)	Total activity
Crude extract	300	11	(3·1)	(0·28)	(930)
"Membrane fraction"	68	10·5	(10·4)	(1·0)	(710)
'Triton X-100' supernatant	86	2·1	7·6	3·6	655
DEAE-cellulose eluate	53	0·2	5·7	27·5	302
DNA column eluate	12	0·06	8·1	135·0	98

About 20 g *E. coli* H 560 cells were washed twice and resuspended in 150 ml. of a 20 per cent sucrose solution buffered by 0·05 M MOPS–0·005 M EGTA (*p*H 7·2). Lysozyme (30 mg) was then added, and the cell suspension stirred overnight in the cold room. 'Brij 58' (2 per cent in 150 ml. water) was added together with $MgSO_4$ (final concentration: 0·002 M). The resulting viscous lysate was treated for 10–20 s with a sonifier. The cells' débris was sedimented at 30,000*g* for 20 min, resuspended in 50 ml. of the MOPS-EGTA buffer and again pelleted. The washed débris was then homogenized in 50 ml. standard buffer (0·05 M Tris–HCl–0·001 M EDTA–0·01 M mercapto-ethanol, *p*H 7·6). This suspension was slowly stirred in the cold room after addition of enough 'Triton X-100' to give a detergent/protein ratio of about 0·25. After 40–60 min the insoluble material was removed by centrifugation (100,000*g*; 30 min). Most of the DNA polymerizing activity (70–90 per cent) was found in the supernatant. This fraction was applied to a DEAE-cellulose column (5 cm × 10 cm) previously equilibrated to standard buffer. The column was washed with 0·25 M NaCl in standard buffer and the enzymatic activity eluted with 0·35 M NaCl. The most active fractions of the DEAE-cellulose eluate were combined, dialysed against standard buffer and adsorbed to a DNA column. In this column circular single stranded phage fd DNA is immobilized in agar beads (1 mg fd DNA/g wet agar; unpublished results of Bonhoeffer and Schaller). More than 95 per cent of the protein applied to the column were not adsorbed or can be washed off with standard buffer. The remaining proteins including DNA polymerase II were eluted by a salt gradient. For unknown reasons 60–70 per cent of the enzymatic activity applied to the column are not recovered in the eluate. Experiments with the DEAE-cellulose enzyme fraction gave essentially the same results as those reported below for the DNA column enzyme fraction.

Enzyme assay. Total volume of 0·2 ml. contained: 0·05 M Tris-HCl (*p*H 7·6), 0·005 M mercaptoethanol, 0·008 $MgSO_4$, 2×10^{-5} M each of dATP, dGTP, dCTP and ^{3}H-dTTP (100 μCi/μmole). The mixture was incubated at 37° C for 30 min. Because the membrane associated enzyme is active for only a few minutes, no precise incorporating activities can be given for the crude extract and the membrane fraction. The data shown are based on the total incorporated radioactivity during the lifetime of the membrane system. One enzyme unit is defined as the activity which incorporates 1 nmole ^{3}H-TTP into acid precipitable material (in 30 min at 37° C).

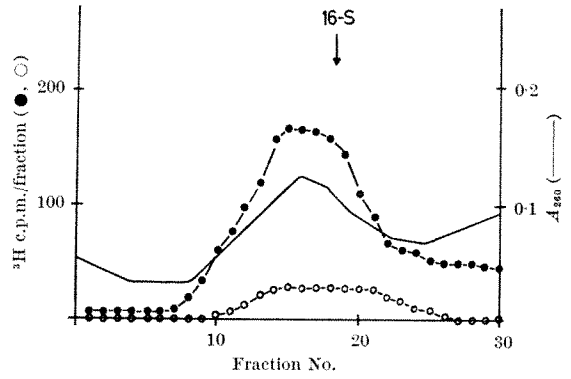

Fig. 3. Alkaline sucrose gradient analysis. About 0·8 mg *E. coli* DNA were treated with 10 units[8] exonuclease III for 45 min at 37° C. The DNA solution was then mixed with an equal volume of water saturated phenol and precipitated with isopropanol in the cold. Portions of 20 μg *E. coli* DNA were then added to reaction mixtures of the composition described in Table 2. NaOH (final conc. 0·2 M) was added to stop the reaction. Alkaline sucrose gradients: linear gradients from 20 per cent to 5 per cent sucrose–0·5 M NaCl–0·2 M NaOH (*p*H 12·5). Sedimentation: 14 h at 25 r.p.m. in the 'SW 27' rotor of the Spinco centrifuge. Sedimentation is from right to the left. The sedimentation marker is circular ^{32}P-labelled single stranded φX-DNA[10]. ○—○, DNA, labelled during a 2 min incubation period; ●—●, DNA, labelled during a 40 min incubation period.

was also used as primer for the experiment shown in Fig. 3. Even after short incubation periods (2 min) the radioactive (that is, *in vitro* synthesized) DNA sediments in an alkaline sucrose gradient with the bulk of the primer DNA, suggesting that the new DNA is covalently linked to pre-existing DNA strands. In another experiment the same exonuclease III treated DNA preparation was used for an experiment in which bromodeoxyuridine triphosphate replaced TTP and ^{3}H-dCTP replaced ^{3}H-TTP in the reaction mixture of Table 2. After incubation for 160 min, enough CsCl was added to the reaction mixture to give a density of 1·72 g/cm^3. The sample was then centrifuged near equilibrium. The result (Fig. 4) shows that the radioactive DNA appears at positions in the gradient where DNA with long segments of bromouracil containing polynucleotides is expected to band.

Table 2. SYNTHESIS OF DNA BY DNA POLYMERASE II

Complete system: 2×10^{-5} M each of dATP, dGTP, dCTP and ^{3}H-TTP (50 μCi/μmole) in 0·08 M KCl–0·045 M Tris-HCl (*p*H 7·6)–0·005 M $MgCl_2$–0·005 M mercaptoethanol in a total volume of 0·3 ml. plus 4 μg sheared calf thymus DNA and 0·2 μg of an enzyme preparation eluted from the DNA column. The mixture was incubated at 37° C for 30 min.

DNA Polymerase II in *pol A*$^+$ Cells

The sensitivity of DNA polymerase II towards *p*-chloromercuribenzoate can be used to screen extracts of bacterial cells for the presence of the enzyme; the difference between the incorporating activity in the presence and in the absence of the mercuri compound should correspond to the activity of DNA polymerase II. The data of Table 4 show that in a total extract of an endonuclease I$^-$, *pol A*$^+$ strain such a difference is not detectable because of the high level of DNA polymerase I. In the membrane fraction, after three cycles of washings with the MOPS-EGTA buffered sucrose solution, a significant fraction of the incorporating activity can be inhibited by *p*-chloromercuribenzoate. Table 4 shows that the activity of DNA polymerase II amounts to 1–2 per cent of the total DNA polymerizing activity of a *pol A*$^+$–*E. coli* cell extract.

Table 3. PRIME DEPENDENCE OF DNA POLYMERASE II

DNA	Approximate molecular weight	Treatment	^{3}H (c.p.m.) incorporated DNA polymerase I	II
E. coli DNA	30×10^6	—	8,772	51
E. coli DNA	30×10^6	Pancreatic deoxyribonuclease	10,587	151

No	—	—	67	<10

The enzymes are tested in the conditions described in the legend to Table 2. 8 μg of the various DNA species are added to the reaction mixture.

Table 4. RELATIVE ACTIVITY OF DNA POLYMERASE II

	Active enzyme units (total activity) No pCMB	10^{-3} M pCMB
Total cell lysate	93,950	93,910
MOPS–EGTA washed débris	3,680	2,235

10 g *E. coli* H 512 cells (*endo I*$^-$, *pol A*$^+$) were lysed with lysozyme and 'Brij' as described. The débris was washed three times with MOPS–EGTA buffered 20 per cent sucrose solution. Enzyme activity was tested as described in Table 2.

DNA polymerase II does attach to single stranded DNA (making the fd DNA column useful in the isolation procedure) and to double stranded DNA (the enzyme also binds to large molecular weight thymus DNA immobilized on a cellulose matrix)[11]. But neither single stranded DNA (linear or circular) or high molecular weight DNA is an effective primer of the polymerization catalysed by DNA polymerase II. Exonuclease III, on the other hand, converts an otherwise poor primer DNA into an effective template for the enzyme; it seems therefore that DNA polymerase II (like all the other known DNA polymerases) needs an end (presumably the 3′-OH end) of a polynucleotide strand as well as a complementary template strand for its function. Endonucleolytically nicked DNA duplexes do not prime the polymerization reaction of DNA polymerase II, probably because this enzyme lacks the exonucleolytic activity essential for the "nick translation" of DNA polymerase I (see ref. 4). From the limited data collected so far it seems that the DNA polymerase II resembles the T4 DNA polymerase described by Goulian, Lucas and Kornberg[12], an enzyme which has been shown by genetic analysis to be the "replicase" for phage T4 DNA[13]. DNA polymerase II is the only DNA synthesizing activity in *Pol A*$^-$ strains which can be

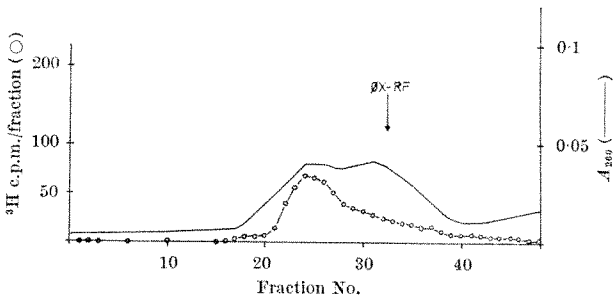

Fig. 4. CsCl equilibrium analysis. The radioactive bromodeoxyuridine labelled *E. coli* DNA in a final volume of 3·2 ml. (initial CsCl density: 1·72 g/cm^3) was centrifuged for 44 h at 35,000 r.p.m. in the 'SW 65-rotor' of the Spinco centrifuge. Density marker is ^{14}C labelled φX-RF DNA ($\varrho = 1·705$ g/cm^3)[10].

released in an active form from the membrane structure. Whether it is the only polymerizing enzyme on the replication site cannot be decided yet. It is feasible that other enzymes lose their activity during the biochemical manipulations.

Dr H. Hoffmann-Berling provided the bacterial strains used in this work. I thank Mrs M. Kurth for technical assistance, Dr H. Schaller for gifts of exonuclease III and bromodeoxyuridine triphosphate, and my colleagues at the Friedrich-Miescher-Laboratorium for comments on the manuscript.

Epstein–Barr Virus in Burkitt's Lymphoma and Nasopharyngeal Carcinoma

Serological tests on 96 Burkitt lymphoma patients reveal antibody activity against virus-determined membrane antigen and viral capsid antigen while nucleic acid hybridization results on Burkitt's lymphoma and nasopharyngeal carcinoma add confirmatory evidence of an intimate association between the viral genome and the two diseases.

Antibodies to EBV associated Membrane and Viral Capsid Antigens in Burkitt Lymphoma Patients

THE sera of Burkitt lymphoma (BL) patients contain antibodies to Epstein–Barr virus (EBV) associated membrane antigens which may be revealed by membrane immunofluorescence tests[1–3]. Because the virus is ubiquitous and appropriate control subjects have not been studied, it has not been known whether this serological activity is particularly associated with the BL disease. We have investigated the serological reactivity against the EBV-associated membrane antigens and the EB viral capsid antigens (VCA) in all the BL patients seen at the Kenyatta National Hospital between 1966 and 1969, in comparison with various controls.

Sera which react with living biopsy BL cells are obtained more frequently from BL patients in long-term remission after chemotherapy than from donors with growing lymphomas[1–3]. Unless the patients have received many transfusions, positive sera do not react with red cells or normal bone marrow cells of the BL biopsy donors, or with normal lymph node or leukaemic cells of other subjects. Positive sera are also encountered at a low frequency among Africans with other neoplastic diseases and among healthy Africans. Established lymphoblastoid cell lines, derived from BL biopsies, provided more readily available and more regularly reactive target cells than biopsies[4,5], particularly if kept in culture conditions favouring membrane antigen expression[6]. Because the antibody activity was found in 7S IgG[4,7], this fraction was isolated from isoantibody-free BL sera and coupled to fluorescein isothiocyanate (FITC), thus converting the previous indirect test into a direct reaction[8,9]. Sera could now be screened for cross-reactivity in blocking tests with the labelled antibodies in the reference conjugates. This reaction was specific: it was blocked by unconjugated BL sera, but not by membrane-reactive, anti-human species specific antibodies[10] or poly-specific HL-A antibodies from frequently transfused donors[9]. The membrane sites reacting with anti-HL-A and anti-species antibodies are therefore distinct from the sites that reacted with the BL conjugates.

A comparison[5] between the cell membrane reactivity of different BL-derived cell lines, and the frequency of cells containing EB-viral capsid antigens (VCA), as defined by the Henle test[11,12], revealed that only lines with more than 1 per cent VCA-positive cells showed significant numbers of membrane antigen (MA) positive cells. Commonly there were approximately ten times more MA than VCA positive cells. This suggested that MA is determined by EBV, but indicated also that anti-MA and anti-VCA antibodies were distinct. This was further shown by absorption experiments and by the occurrence of "discordant" sera with predominantly one type of reactivity[13]. More recently, MA was induced by infecting MA-negative cells with EBV concentrates[14,15] or by exposure to lethally X-irradiated, EBV-carrying cultures[4]. Because the virus neutralizing titres of "discordant" sera paralleled their anti-MA and not their anti-VCA reactivities[16], it was suggested that MA represents viral envelope components in the cell membrane, in analogy with the herpes simplex system[17].

The blocking of direct membrane fluorescence has not been extensively evaluated with regard to disease-related patterns. In a preliminary study[9] eighteen of twenty African BL sera showed a high blocking activity against the FITC-conjugated IgG fraction from a BL patient (F-Mutua). The two sera with low activity came from a single patient, one taken in long term remission shortly before tumour recurrence, and the other when the patient was moribund. All 20 sera had high anti-VCA titres. Sera from unmatched control subjects with few exceptions had low MA-blocking activity. Nasopharyngeal carcinoma (NPC) was the most important exception. African and Chinese NPC patients showed regularly high anti-MA reactivity[9,18]. This corresponds with the regularly high anti-VCA titres found in NPC patients[19] and their fre-

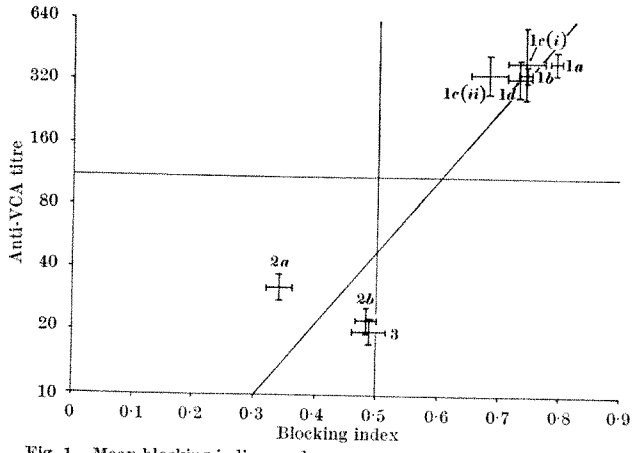

Fig. 1. Mean blocking indices and mean anti-VCA titres, with standard errors, for all groups involved in this study. An arithmetic mean of the blocking indices of all sera was calculated for each serum group, together with the standard error of the mean, assuming normal distribution of the observations. VCA titres were transformed into logarithmic units. The arithmetic mean and standard error of the logarithmic values were calculated, assuming normal distribution as above. The geometric mean titre obtained by conversion of the log titres was used for the comparison between the groups. To calculate regression and correlation between the MA and VCA tests, MA (BI) values were entered on a linear abscissa and VCA titres on a logarithmic ordinate. 1*a*, BL, pretreatment sera; 1*b*, BL, randomly selected sera; 1c (i), BL, tumour-free for 6 months; 1c (ii), BL, tumour-free for 1 yr; 1*d*, BL, tumour-bearing for at least 3 months; 2*a*, BL patients' relatives, age unknown; 2*b*, BL patients' relatives, age known; 3, tonsillitis cases.

quent reactivity in immunoprecipitation tests against an EBV-associated soluble antigen[20,21].

Our study was undertaken to assess the anti-MA and anti-VCA levels in BL patients in different disease stages, in comparison with their healthy blood relatives and Africans with chronic tonsillitis.

Selection of Sera

Ninety-seven histologically confirmed BL cases were seen at the Department of Head and Neck Surgery, Kenyatta National Hospital, Nairobi, from February 1966 to December 1969. Sera were available from ninety-six of the ninety-seven patients. They were grouped as follows:

Group 1*a:* Sera of fifty-six patients taken immediately after admission, before treatment.

Group 1*b:* One randomly picked serum from each of the ninety-six patients, assembled by a table of random numbers, applied to lists of available sera from each individual.

Group 1c (i)*:* Sera of nine patients without clinically detectable tumour for 6 months at the time of bleeding.

Group 1c (ii)*:* Sera of ten patients without detectable tumour for 1 year at the time of serum sampling. One patient here is represented twice; his tumour recurred 4 years after the initial treatment and regressed again after chemotherapy.

Group 1*d:* Sera of eighteen patients with persisting finally lethal tumours, taken at least 2 months before death, and at least 3 months after first admission.

Groups 2*a and* 2*b:* Sera from the families of BL patients, mostly siblings and parents, but also some neighbours. No donor is represented by more than one serum. The age and sex distribution of sixty-three relatives (group 2*b*) is known. For another group of sixty-three donors, designated 2*a*, this information is not available.

Group 3*:* Sera from fifty-three tonsillitis cases seen at the Kenyatta National Hospital during the same period as the BL patients. These were not all tonsillitis cases seen, for only occasional patients were bled, on request from Stockholm.

Further information on the groups is given in Table 1. Because of insufficient quantities of serum, ten patients in group 1*a*, six in 1*b*, two in 1c (i), two in 1c (ii), two in 1*d*, eight in 2*a* and *b* and eight in group 3 were not tested for anti-VCA titres.

Test Procedures

In the test for antibodies to MA, EBV-carrying lymphoblastoid cell lines established from BL biopsies[22] were used as target cells in the direct membrane immunofluorescence reaction[8,9]. IgG, conjugated with fluorescein isothiocyanate (FITC), from the BL patient Mutua (Kenya Cancer Council registry number 454) served as reference reagent. Mutua has been in total tumour regression since 1965 and his serum is free of detectable isoantibodies[4]. It reacts with at least two antigenic receptors on the surface of BL cells in EBV-carrying cultures[23].

Cultures containing 40–80 per cent membrane reactive cells were selected by a pretesting procedure[9], and incubated with a non-blocking reference serum, a known blocking serum (the unconjugated serum of Mutua), and with the test sera. After incubation and washing, the cells were exposed to the conjugate as described[9]. A blocking index (BI) was calculated by subtracting the proportion of positive cells in the test-serum exposed sample from the proportion of positives in the sample exposed to the conjugate alone, and dividing the difference by the latter figure. The negative and positive reference sera served as controls for the technical quality of the test.

Each serum was tested in at least three independent tests. The reactions were classified according to criteria described previously[9]. For each serum, an arithmetic mean BI was calculated.

The procedure for testing anti-VCA antibody involved the preparation of acetone-fixed smears from the EBV-carrying E3 Bline (BL), maintained for 3 days on arginine-free medium, and the titration of antibodies in indirect immunofluorescence tests as described elsewhere[11,12].

Elevated EBV-associated Antibody Levels in BL Patients

The arithmetic mean BI and the geometric mean anti-VCA values of the various groups of sera are presented in Fig. 1. The two tests correlate strongly ($r = 0{\cdot}97$; regression equation $\log_2(\text{VCA}/10) = 11{\cdot}8\ \text{BI} - 3{\cdot}6$). All BL groups gave high mean values in both tests, differing significantly from the two BR (Burkitt patients' relative) groups and from the tonsillitis group. The patients entering group 1*a* were subdivided according to sex and age and comparisons were made between sera stored for different times. No significant differences were found. The BL patient categories gave similar results with regard to mean BI or mean VCA titre. The differences between the control groups were also insignificant. By contrast, the differences between any of the large BL groups (1*a* or 1*b*) and any of the control groups were highly significant.

Fig. 2 presents in a scatter diagram the relation between BI and anti-VCA values for individual sera. As in previous studies[9,18], the two serological reactions correlate nicely ($r = 0{\cdot}79$ for 253 sera; regression equation of $\log_2(\text{VCA}/10) = 9\ \text{BI} - 2{\cdot}5$).

For a schematic comparison with earlier data, the "four quadrant" diagram has been used as previously[18], with an arbitrary subdivision between high and low blocking indices (0·5 borderline) and anti-VCA titres (low ≤ 80, high ≥ 160) (Table 2).

Table 1. AGE AND SEX DISTRIBUTION OF SERUM DONOR GROUPS

Group	Number of serum donors	Male/female ratio	Per cent of patients in the age range (years) 0–2	3–4	5–6	7–8	9–10	11–12	13–14	15–16	17–18	19–20	> 20
1*a* (untreated BL)	56	1·24	2	16	38	25	13	5	0	2			
1*b* (randomly assembled BL sera)	96	1·53	2	11	38	22	16	5	1	3	1		
1c (i) (BL in regression for about 6 months)	9	3·5		11	33	45	11						
1c (ii) (BL in regression for about 1 year)	10	4·0		10	30	40	20						
1*d* (BL with persisting tumour)	18	2·6		11	33	28	16	6		6			
2*a* (relatives of Burkitt patients, first group)	63	Unknown			Unknown					Unknown			
2*b* (relatives of BL patients, second group)	63	0·75	3	15	6	11	14	11	2			3	35
3 (African tonsillitis patients)	53	0·90		6	16	19	12	35	10	2			

Groups 2*a* and *b* were site-matched with some of the BL cases and district-matched to the entire BL population. Group 3 came from other areas.

Possible Biological Interpretations of Serological Data

Although the antibodies measured by the MA and VCA tests are directed against different antigens[13,23,25], there is a good correlation between the two antibody levels in most human sera[9,18,24]. Discordant minorities exist[13], however, and their study is important because they may contribute to a better understanding of virus–host relationships.

Table 2. DISTRIBUTION OF ANTI-VCA TITRES AND BLOCKING INDICES COMPARED WITH PREVIOUSLY PUBLISHED DATA

(*a*) Present material (BL: Burkitt group 1*b*; BR: Burkitt relatives, groups 2*b*+2*a*; T: tonsillitis, group 3).

Blocking index	VCA titre: High (≥160) BL	BR	T	Total per cent	Low 0≤80) BL	BR	T	Total per cent
High (≥0·5)	78	8	1	87 (34 per cent)	8	29	20	57 (23 per cent)

Ref.:								
High (≥0·5)	37	40	41	34	8	8	10	23
Low (<0·5)	11	10	6	2	44	32	43	41

* 279 sera, including African and non-African donors with Burkitt's lymphoma, nasopharyngeal carcinoma, infectious mononucleosis, and other malignant and non-malignant diseases.

† 151 sera from African and non-African cases of Burkitt lymphoma, nasopharyngeal carcinoma, other head and neck tumours, infectious mononucleosis and normal African and non-African controls.

‡ 191 sera from African and Chinese nasopharyngeal carcinomas, Indian oro- and hypopharyngeal carcinomas, and African controls with malignant and non-malignant diseases.

In this series, 75 per cent of all sera gave concordant results in the two tests (Table 2) whereas 25 per cent were discordant according to previously defined criteria. In earlier tests, the frequency of concordant sera was 81 per cent[9], 82 per cent[24] and 84 per cent[18] respectively. The somewhat lower degree of concordance observed in our series reflects different compositions of the serum collections. This series, which is the first all-African collection analysed, contains an unusually large number of sera with low anti-VCA titres and high blocking indices (fifty-seven sera, 23 per cent). Of these fifty-seven sera, twenty-nine were from Burkitt patients' relatives and twenty from tonsillitis cases. A prevalence of low anti-VCA and high anti-MA levels was previously noted[13] in a small series of sera from Burkitt patients' relatives. The presence of several such sera in the tonsillitis group suggests that this pattern is not restricted only to the relatives. The opposite discordance, high anti-VCA titres and low anti-MA values, was frequently seen in patients with large nasopharyngeal carcinomas[18], presumably because of adsorption of anti-MA antibodies to the tumour. The absence of NPC patients from this material may explain the small number of such sera (five sera, 2 per cent).

A comparison of BL patients and various African controls has previously shown[19] that the geometric mean anti-VCA titre of the patients was eight times higher than that of the controls. A difference of the same order was also found in this study. Moreover, a significant elevation of the anti-MA antibody level was noted. Whereas the mean BI values of all BL groups differed significantly from the controls, there were only slight differences between the different BL groups. The slightly lower mean BI in patients in remission for 1 year may reflect a decline in antigenic stimulation. The temporary rise of anti-MA levels after local radiotherapy[26] suggests that continued antigenic stimulation may be important for the maintenance of high anti-MA levels.

Although differences in mean BI obtained with undiluted sera are no doubt real, high blocking activities observed in these conditions do not necessarily denote equal levels of antibodies. Studies in progress (P. G., G. K., P. C., G. H., and W. H., in preparation) have shown that

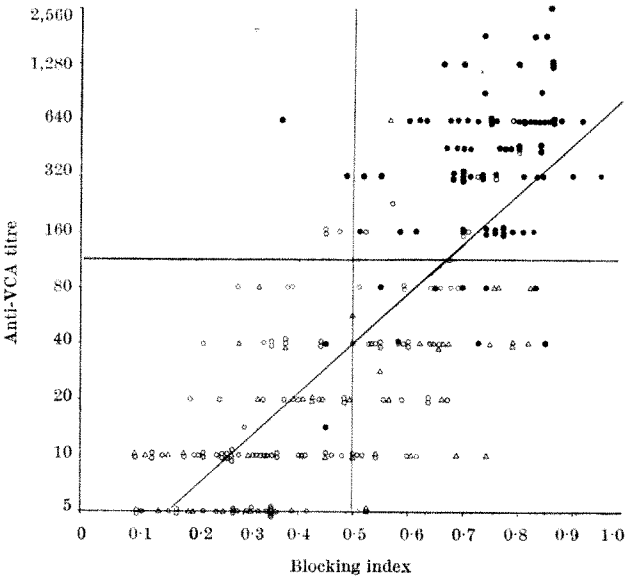

Fig. 2. Scatter diagram of BI and anti-VCA values obtained with BL group 1*b*, the two groups of Burkitt patients' relatives (2*a* and *b*) and African tonsillitis patients (group 3). Each point represents an individual serum. All sera were obtained from different donors. To avoid double representation of BL donors that entered more than one BL category, only the large, randomly assembled group 1*b* is shown together with the three control groups (2*a*, 2*b* and 3). ●; BL 1*b*; ○, BL relatives 2*a*+2*b*; △, tonsillitis patients.

undiluted BL sera with high blocking indices may yield blocking titres ranging from 1 : 2 to 1 : 400 upon dilution, taking a BI of 0·50 as the titration endpoint. The relationship between blocking titres and clinical history will be described elsewhere.

EBV DNA in Biopsies of Burkitt Tumours and Anaplastic Carcinomas of the Nasopharynx

A TEST system involving DNA–DNA hybridization has recently been described which makes possible the detection of Epstein–Barr virus (EBV) nucleic acid in tumour cells[1]. This method has been used to demonstrate EB viral genome equivalents in the "virus-free" Raji line of Burkitt tumour origin[1]. The presence of viral nucleic acid in these non-virus producing cells revealed that EBV can persist in a masked form, thus exhibiting characteristic features of well known members of the DNA tumour virus group.

Several observations have suggested a close association of EBV with Burkitt's lymphoma (BL) of African children. A high proportion of cells from biopsies was shown to exhibit EBV-determined cell membrane antigens[2,3] unless these were blocked by the patient's antibodies. While EB viral antigens were rarely detectable in biopsy cells, they appeared regularly in a proportion of the cells placed in culture, often within a few days[4]. Clones cultured in the presence of antibodies to EBV from singly picked cells of established continuous BL cultures all revealed the presence of EBV in a small fraction of the cells[5]. All African BL patients have shown antibodies to EBV[2,6,7] usually at high titres, whereas among African control children antibodies are present generally at low titres, or, in a few, absent altogether. High levels of EBV-related antibodies are also found in most patients with anaplastic nasopharyngeal carcinomas (NPC) but not with other carcinomas of the head and neck[8–10].

To elucidate further the association of EBV with BL and NPC, we tried to detect and quantify EB viral DNA in tumour cells by nucleic acid hybridization. We found that DNA from BL and NPC biopsies always annealed with EBV DNA to a greater extent than DNA from other malignant tumours from control individuals with antibodies to EBV-related antigens.

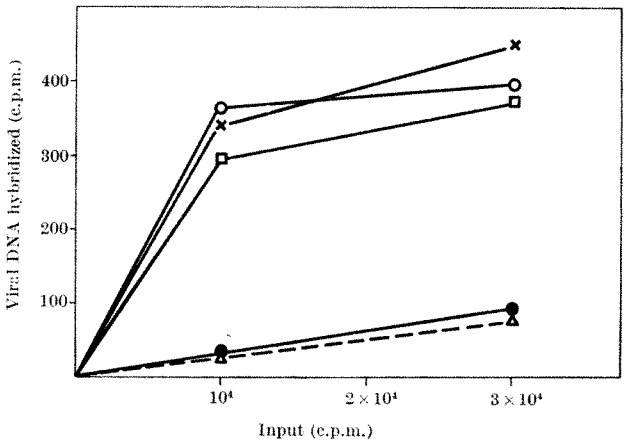

Fig. 1. Hybridization of EBV ^{3}H-DNA with DNA from biopsies of KCC 1140 (×—×), KCC 1124 (○—○), KCC 1097 (□—□), SÖD (△ - - - △), and with DNA from KB cells (●—●).

Tumour Cells and DNA Preparations

Biopsies were kept frozen from the time of surgical removal until DNA extraction. Biopsies from "control tumours" were kindly provided by Dr Gerlach, Würzburg (SAU), Dr Waubke, Giessen (SCH and BRÜ), Dr Johansson, Stockholm (SÖD), and Dr von Bülow, Tübingen (Marek's disease). All other biopsies were collected at the Kenyatta National Hospital, Nairobi. The diagnosis of every tumour was confirmed by histological examination. Sera from all but two patients were tested for antibodies to EB viral capsid antigens[7,8] and to EBV-induced early antigens[11] by the indirect immunofluorescence technique, and for antibodies to EBV-determined cell membrane antigens[3] by blocking of direct immunofluorescence[12].

For DNA extraction about 0·3–0·5 g of tumour material was thawed and ground with purified sea sand (Merck, Darmstadt). Thereafter 10 ml. of 0·01 M *tris*(hydroxymethyl)-aminomethane chloride (Tris), *p*H 8·1, containing 1 per cent sodium dodecyl sulphate was added[13]. This was followed by digestion with 1 mg/ml. of pronase P (Serva-Chemie, Heidelberg) for 60 min at 37° C. The nucleic acids were extracted by three consecutive phenol treatments[13]. Extensive dialysis against 0·1 × SSC (0·015 M NaCl – 0·0015 M citrate) was followed by treatment with ribonuclease (20 μg/ml., heated for 10 min to 80° C before use). The samples were subjected to another phenol extraction and dialysed against 0·1 × SSC. ^{3}H-labelled EBV DNA was prepared and purified by sucrose velocity sedimentation as described[1,14]. The dialysed fractions were lyophilized, redissolved in 0·1 × SSC, again dialysed against 0·1 × SSC, and examined for absorbance between 220 and 300 nm.

^{3}H-labelled herpes simplex virus (HSV) DNA was extracted from partially purified HSV by the same procedures as reported for EBV[14]. The infected cells were exposed to 1 μCi/ml. of ^{3}H-thymidine (specific activity 20·1 Ci/mmole) during the viral DNA replication for a period of 20 h.

DNA of human KB cells was included in all hybridization tests for control purposes. Occasionally, we also examined DNA from Nil-2 cells of Syrian hamster origin[15], cytomegalovirus-infected Wi-38 cells, and the EBV-carrying D 75 line of lymphoblasts established by exposure of peripheral leucocytes to EBV[16]. Details of denaturation and DNA–DNA hybridization procedures have been given[1,13].

Hybridization with EB Virus ^{3}H-DNA

Table 1 summarizes the results of four different hybridization tests, each involving DNA from several sources, as well as data on biopsy donors. It shows that the DNA

The filters containing cellular DNA (100 μg/membrane) were incubated with 20,000 c.p.m. of EBV ^{3}H-DNA. The specific radioactivities of the viral DNA preparations used were 22,500 c.p.m./μg (test No. 1), 11,000 c.p.m./μg (test No. 2), 10,600 c.p.m. (test No. 3), and 9,150 c.p.m./μg (test No. 4). The serological data represent mean values of multiple tests.

derived from biopsies of Burkitt tumours, as well as anaplastic carcinomas of the nasopharynx, annealed with EBV DNA to a greater extent than DNA from other tumours and cultured cells of virus-negative lines examined. The specific radioactivities of the viral DNA preparations used were different in each of the four experiments. To compare the results of the four tests, it seemed most convenient to estimate the viral genome equivalents per cell[1]. We therefore determined whether or not the hybridization tests were performed under saturating conditions. DNA from biopsies of patients KCC (Kenya Cancer Council) No. 1140, 1124, 1097 and SÖD, as well as from human KB cells, was annealed with 10,000 and 30,000 c.p.m. of EBV ^{3}H-DNA (Fig. 1). The small amount of viral DNA available precluded the use of additional inputs, as well as further saturation experiments. The result showed that the hybridization of DNA from Burkitt tumours and anaplastic carcinomas of the nasopharynx reached a plateau between 10,000 and 30,000 c.p.m. This, in addition to previous evidence obtained in similar conditions[1], supported the assumption that the DNA in the four tests presented in Table 1 annealed with saturating amounts of viral ^{3}H-DNA. This provided the basis for calculation of viral genome equivalents per cell[1].

The estimation of viral genome equivalents showed that the Burkitt tumours contained between two and twenty-six, and the nasopharyngeal carcinomas between one and nineteen per cell. From two BL patients, two different tumours were tested, both with typical histology. The ovarian tumour of patient KCC 1080 contained a similar number of genome equivalents to the left orbital tumour which was biopsied 7 months after the first. Similarly, the ovarian and maxillary tumours of patient KCC 1140 hybridized with EB viral DNA to nearly the same degree. By contrast, the DNA of all other tumours, including Marek's disease tumours of chicken, failed to anneal to a greater extent than the DNA from human KB cells, Nil-2 cells of Syrian hamster origin (negative controls), or cytomegalovirus-infected Wi-38 cells, of which nearly every one showed cytopathic changes before DNA extraction. The DNA of the D 75 line with 2 to 3 per cent EBV antigen-producing cells (positive control) hybridized with about 17 per cent of the input EBV DNA.

Hybridization with Herpes Simplex Virus ^{3}H-DNA

In order to further establish the specificity of the DNA–DNA hybridization procedure, selected samples of DNA from biopsies and tissue culture cells were annealed with HSV ^{3}H-DNA (Table 2). The high specific radioactivity of the viral DNA increased the background annealing

Table 2. HYBRIDIZATION OF HERPES SIMPLEX VIRUS ^{3}H-DNA WITH CELLULAR DNA OF VARIOUS ORIGIN

100 μg cellular DNA per filter were hybridized with 20,000 c.p.m. of HSV–DNA. Specific activity of HSV–DNA 51,000 c.p.m./μg.

considerably. In spite of some variations, all specimens hybridized approximately within the same range. The positive control (DNA from HSV-infected Nil-2 cells) annealed with about 17 per cent of the input viral DNA. DNA from D 75 cells which showed a high degree of homology with EBV DNA (Table 1) failed to react with HSV–DNA.

Antibodies to EBV Related Antigens

Antibodies to viral capsid antigens ranged in titre from 1 : 80 to 1 : 2,560 in the BL and NPC patients, but only from 1 : 10 to 1 : 195 in the patients with other tumours (Table 1). Antibodies to early EBV-induced antigens ranged from 1 : 5 to 1 : 640 in the BL and NPC patients but were absent in the control tumour patients. Antibodies to EBV-determined cell membrane antigens, as measured by the blocking index (BI), were at high levels (BI > 0·5) in eight of the ten BL patients, as well as in eight of the ten NPC patients, but in only two out of nine of the other biopsy donors tested. Although the absence of viral genome equivalents in the control tumour biopsies correlates well with the generally low antibody levels of their donors, and the presence of such equivalents in the BL and NPC biopsies with the generally high antibody levels in these patients, there was no clear-cut relation between the number of equivalents found in biopsies and the concentration of any one of the antibodies measured by the three methods.

Interpretation

All the BL and NPC biopsies—but none of those used as controls—contained EBV DNA in varying quantities. The specificity of the observed interactions seems clear from the fact that no hybridization was detectable between EBV DNA and DNA from cytomegalovirus-infected cells or from Marek's disease tumours, nor between herpes simplex virus DNA and DNA from BL and NPC biopsies. This is consistent with the lack of significant antigenic crossing between EBV and other members of the herpes group[6].

The number of EBV genome equivalents per cell varied from one to twenty-six in tumours of different patients. These might be underestimates depending on the representation of stroma or other non-tumour cells in the biopsies. Indeed, in the case of NPC, it is still not clear whether the viral DNA was derived from the anaplastic carcinoma cells or the lymphoid elements present to varying extents, or both. It is of interest that the number of viral genome equivalents were of the same order in different tumours of given BL patients biopsied at different times. This suggests a stable virus–host relationship in individual patients which is in line with previously reported observations[4]. The clonal nature of this tumour, as shown by Fialkow *et al.*[17], also agrees with these findings.

It has been suggested that after primary infections, whether or not accompanied by signs of classical infectious mononucleosis, EBV persists, presumably in the lymphoreticular system; this would account for the persistence of antibodies to VCA for years, if not for life, and the frequent emergence of the virus in cultures of peripheral leucocytes of healthy donors or patients with various diseases[18]. The presence of EBV genome equivalents in Burkitt's lymphomas and nasopharyngeal carcinomas might merely denote an extension of the persistent infection to the tumours, leading to increased antigenic stimulation and with it to the generally high levels of antibodies to EBV-related antigens in patients with these malignancies. All tested donors of the control tumour biopsies, however, had antibodies to VCA and therefore were presumably also carriers of EBV. Further, the numbers of EB viral genome equivalents per cell at apparently constant levels seem to be incompatible with a merely casual persistent infection of the tumours but rather suggest an intimate interaction of viral DNA with most, if not all, tumour cells.

In conclusion, we have provided direct evidence for the regular presence of EBV nucleic acid in biopsies of Burkitt's lymphomas and anaplastic carcinomas of the nasopharynx. The DNA–DNA hybridization seemed to be specific for EBV DNA and up to 26 genome equivalents were estimated to be present per cell.

H. z. H. and H. S.-H. thank Dr Eberhard Wecker for discussion and Mrs Sharon Hermen for technical assistance. Origin of Mammalian Trypanosomes which Develop in the Anterior-station of Blood-sucking Arthropods

by
P. T. K. WOO*
Department of Zoology,
University of Guelph,
Guelph, Ontario

Two hypotheses have already been advanced on the origin of the pathogenic trypanosomes of African mammals. A third is here proposed, in which it is suggested that they originated recently from leech-transmitted trypanosomes of aquatic reptiles in the tropics.

It is generally accepted that trypanosomes are monophyletic in origin and were primary gut parasites of invertebrates[1–8]. Two hypotheses have been advanced concerning the origin of the Salivaria, which are trypanosomes that develop in the foregut of the vector and are then injected into the mammalian host (see Fig. 1). Hoare[4,5,9] suggested that these trypanosomes originated recently from the Stercoraria (trypanosomes that develop in the hind gut of the vector and infect the vertebrate host by contamination, see Fig. 2), while Baker[7,8] suggested they were originally trypanosomes of aquatic reptiles which had evolved with their hosts as they colonized the land. I propose that the anterior-station trypanosomes of mammals evolved recently in the tropics from the trypanosomes of aquatic reptiles.

Trypanosomes can be divided into three fairly homogeneous groups based on the kind of vector and the site of development: first, the trypanosomes of aquatic vertebrates (fishes, amphibians, and reptiles), which develop in the anterior-station of leeches, infection of the vertebrate host is via the proboscis of the leech during feeding; second, the trypanosomes of birds, mammals and of some reptiles, which develop in the posterior-station of arthropods, the vertebrate host is infected by faecal contamination of the wound made by the arthropod during feeding or of the mucous membranes of the oral cavity if infective stages are ingested; third, the trypanosomes of African mammals transmitted by tsetse flies, and *T. rangeli* transmitted by the reduviid bug in South America. These trypanosomes develop in the anterior-station of blood-sucking arthropods and infective stages are inoculated into the final host at the time of the blood meal. The Salivaria are generally considered to differ from other trypanosomes in being more pathogenic to their vertebrate hosts[4,7]. Trypanosomiasis in domesticated animals in Africa has been the subject of intensive study for many years. These trypanosomes are not always highly pathogenic to wild animals in Africa; however, Ashcroft *et al.*[10] pointed out that while some wild animals in Africa are usually killed by *T. rhodesiense* and *T. brucei*, others are usually tolerant or resistant to the infection. Even among the first group, individual animals survive the infection. Nevertheless, it is characteristic of the Salivaria to be more pathogenic than other trypanosomes. Morphologically, trypanosomes of the Salivaria are distinct in that their posterior ends are rounded (except in *T. suis*) and not pointed as in other mammalian trypanosomes[11].

Metabolic studies of blood stages have revealed striking differences between the Salivaria and Stercoraria[12]. Most Salivaria (for example, *T. brucei*, *T. rhodesiense*, *T. evansi*) degrade glucose to a mixture of pyruvic acid and glycerol, but *T. lewisi* and *T. cruzi* convert glucose to a mixture of lactic and acetic acids with the production of large amounts of carbon dioxide. Cyanide does not affect the respiration of *T. rhodesiense* and *T. vivax*, but does affect that of *T. lewisi* and *T. cruzi*. Also, cytochrome pigments were detected in *T. cruzi* and *T. lewisi* but not in *T. congolense*, *T. rhodesiense* or *T. equiperdum*. These metabolic differences have not been observed in the insect or culture forms of the two groups of trypanosomes, which tends to support the view that trypanosomes are monophyletic in origin and that the observed differences in the blood stages are secondary features adapted to conditions in the vertebrate hosts.

Godfrey[13] found that *T. lewisi* had considerably less sphingomyelin and more lecithin than *T. brucei*, *T. vivax*

* Present address: Department of Veterinary Microbiology and Immunology, Ontario Veterinary College, University of Guelph, Guelph, Ontario, Canada.

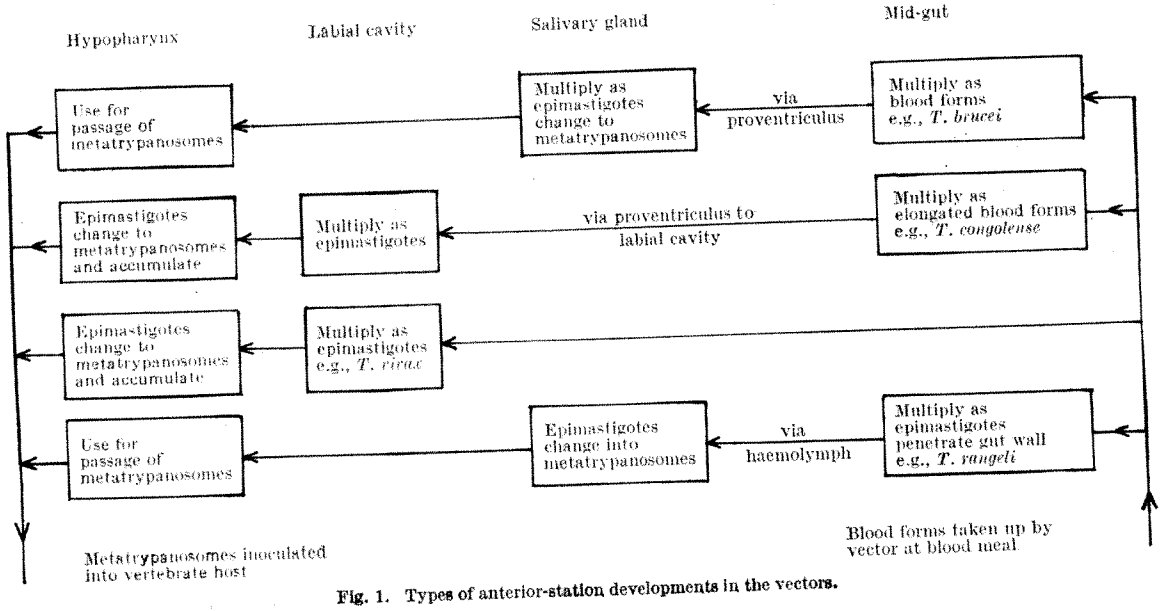

Fig. 1. Types of anterior-station developments in the vectors.

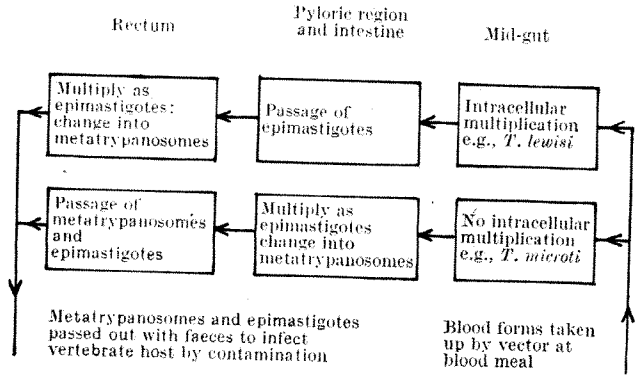

Fig. 2. Types of posterior-station developments in the vectors.

and *T. congolense*. Such differences are not confined to the phospholipids. Jaffe, McCormack and Gutteridge[14] found that the dihydrofolate reductase ". . . of *T.* (*T.*) *brucei*, *T.* (*T.*) *rhodesiense*, *T.* (*T.*) *equiperdum*, *T.* (*D.*) *vivax*, and *T.* (*N.*) *congolense* had closely similar drug sensitivity profiles, clearly distinguishable in certain respects from the reductases of *T.* (*H.*) *lewisi* and *T.* (*S.*) *cruzi*". They further pointed out that this particular protein was mutually indistinguishable among the saliverian species studied.

Although *T. lewisi* phosphohexose isomerase cross-reacts with the antisera to the *brucei* group enzyme (which suggests a close relationship between the Stercoraria and Salivaria) there are differences even between the isomerases of *T. brucei* and *T. equiperdum* and those of *T. gambiense* and *T. rhodesiense*. It is therefore doubtful if isomerase has any phylogenetic significance within a group.

The Salivaria are less host specific: for example, members of the *T. brucei* group can infect rodents, carnivores, ungulates, and primates, whereas most other trypanosomes of mammals (with the exception of *T. cruzi*) have a fairly narrow host range.

The Salivaria are unusually inefficient in infecting their vectors[9,16]. *T. vivax*, which develops in the proboscis of the tsetse fly, often infects only about 20 per cent of flies which have fed on an infected animal. *T. congolense*, which multiplies in the proboscis and mid-gut of the vector, often infects only about 10 per cent of the flies and *T. brucei*, which develops in the mid-gut and salivary glands, is even less infectious. In contrast, those trypanosomes that develop in the posterior-station of insects invariably infect almost 100 per cent of vectors that have fed on an infected animal[4,9].

Most trypanosomes transform into epimastigotes before dividing in the vector[17], but members of the *T. congolense* and *T. brucei* groups multiply as trypanosomes in the mid-gut of the tsetse fly. They are transformed into epimastigotes after migration to the proboscis or salivary glands[18]. All these common features tend to separate the pathogenic trypanosomes of African mammals from members of the rest of this genus.

The Hypotheses of Hoare and Baker

Hoare[4,5,9] suggested that the anterior-station trypanosomes of mammals might come from members of the Stercoraria. He believed that ". . . these pathogenic trypanosomes were originally parasites of wild ruminants, whose development was completed in the posterior-station of some other insect vector which transmitted them by the contaminative method"[9]. The transformation ". . . was affected either directly in the original vector (for example, *T. rangeli* in reduviid bugs) or indirectly, by secondary adaptation to cyclical development in insects that formerly served as mechanical vectors (for example *Glossina*)"[5]. So he is suggesting that the anterior-station trypanosomes of mammals came from a posterior-station trypanosome stock. Hoare[19] suggested that the Salivaria are only gradually becoming adapted to the tsetse fly for transmission, and that they first became adapted to the proboscis, then the mid-gut and finally the salivary glands. Invasion of the salivary glands was recent for Duke[20] showed that many mid-gut infections of *T. brucei* failed to become established in the salivary glands.

Baker[7] has suggested that trypanosomes which use leeches and insects as vectors had a common ancestor that parasitized the gut of the ancestor of both leeches and insects. When the annelids and arthropods diverged in the course of their evolution during the Cambrian period each took along its parasites. The trypanosomes were transferred to vertebrates when leeches and arthropods became blood-suckers. He also offered an alternative[7,8] to Hoare's hypothesis, suggesting that the anterior-station trypanosomes of African mammals represent ". . . the survivors of a line which did evolve from the leech aquatic group along with their vertebrate hosts as they gradually colonized the land"[8].

Hoare's suggestion that the trypanosomes of African mammals evolved from posterior-station forms implies that these trypanosomes develop in the anterior-station of the tsetse fly mainly because of the vector rather than their ancestral origin. *T. grayi* (which morphologically resembles members of the Stercoraria) of crocodiles in Africa is, however, transmitted by *Glossina palpalis*, one of the vectors of the *T. brucei* group. Development of *T. grayi* takes place in the hind-gut of the fly and transmission to a new host is by faecal contamination[3,21]. So it seems that there is nothing about *Glossina* which makes posterior-station development impossible. Adler and Theodor[22] demonstrated that *Trypanosoma platydactyli* of the gecko (*Taranetola mauretanica*) develops in the anterior-station of the sand fly *Phlebotomus parroti*. Recently Anderson and Ayala[23] found that a trypanosome (morphologically similar to members of the Stercoraria) of the toad (*Bufo boreus halophilus*) develops in the hind-gut of the sand fly *Phlebotomus vexator occidentis*. Although *T. rangeli*, a parasite of mammals of tropical South America, develops in the posterior and anterior station of the reduviid bug, infection of the vertebrate host is by way of the mouth parts of the vector. Infective metacyclic forms are produced only after the haemolymph and salivary glands are invaded[24]. This is in contrast to *T. cruzi*, which develops in the posterior-station of the reduviid bug, and in which infection of the vertebrate host is by faecal contamination of the wound made during feeding. Also *T. rangeli* is pathogenic to the vector[24,25], which may indicate a recent association between the reduviid bug and *T. rangeli*. These examples indicate that the site of development of a trypanosome may not depend on the vector, because anterior and posterior-station developments are possible in the tsetse fly, sand fly and reduviid bug.

Morphologically there is little evidence that the Salivaria came from the Stercoraria. If the Salivaria came recently from the posterior-station forms as suggested by Hoare, one would expect to find in African mammals some members of the Stercoraria (which develop in the posterior station of arthropods) with rounded posterior ends. So far as is known, all members of the Stercoraria have pointed posterior ends[11].

Baker[7,8] suggested that the tetrapod ancestors of modern mammals took trypanosomes along with them when they adapted to a terrestrial mode of life. Because the trypanosomes came from a leech–aquatic–vertebrate stock an anterior-station development was retained even after new vectors were secondarily acquired. If we accept Baker's view, the trypanosomes of African mammals have to be considered the oldest group of existing trypanosomes in terrestrial mammals, which makes it difficult to explain why the African trypanosomes are pathogenic to their vertebrate hosts and also have such a wide range of hosts—two factors that are usually associated

with organisms recently adapted to new hosts[4,9,26–28]. Also poor development of the trypanosomes in tsetse flies indicates a recent adaptation to the fly for transmission[4]. If we accept Baker's hypothesis that the tetrapods evolved with their trypanosomes, what were the vectors before the tsetse flies ?

An Alternative Hypothesis

I propose that trypanosomes that develop in the anterior-station of arthropods evolved quite recently from a leech–aquatic–vertebrate stock, perhaps from those of reptiles in the tropics. This hypothesis might explain why African trypanosomes tend to be unusually pathogenic to the vertebrate host and why they have such a wide range of hosts. The fact that they develop poorly in the tsetse fly may indicate a recent adaptation to the fly for transmission, as suggested by Hoare[4,9].

Experimental studies have shown that trypanosomes tend to become increasingly pathogenic while adapting to new hosts. Desowitz and Watson[29,30] have shown that rats can be infected with *T. vivax* if sheep blood or serum is inoculated as a supplement. In their earlier subpassages sheep serum was necessary and none of the rats died from the infection but "the greater percentage of rats which become heavily infected in later rat subpassages indicates that the infection becomes progressively severe"[30]. After thirty-seven subpassages in the rat the strain had lost its dependence on sheep serum[31], and this strain now produces ". . . fulminating lethal infections in that host"[32]. Moreover, *T. lewisi* can infect mice if rat serum is inoculated with it[33]. Lincicome[34] has shown that in calorically restricted mice the number of hosts that developed maximal infections and the intensity of the parasitaemia are increased by subpassaging. Although there was an initial decline in death rates of mice in earlier subpassages there was a definite increase in later subpassages, and this continued to 100 per cent fatality when C3H mice were used instead of albino mice. Also, there was a gradual reduction in the life span of infected animals and a steady diminution of the period over which the maximal infection level persisted.

Although *T. vivax* and *T. lewisi* can be adapted artificially to new hosts (by the inoculation of homologous host serum), the latter species does not lose its dependence on rat serum for survival in the mouse even after it has been subpassed 300 times, while *T. vivax* is able to do without sheep serum after 37 subpassages. This lack of plasticity of *T. lewisi* might suggest that it has been associated with the rat for a much longer time than *T. vivax* has with mammals. Other members of the Salivaria (for example, *T. rhodesiense*, *T. brucei*) are well known for their numerous antigenic changes (or variations) in response to antibodies or chemotherapeutic drugs. It should be noted that antigenic changes occur in *T. lewisi* infections[35], but are limited to two, while those of the Salivaria are believed infinite or at least very large[36,37]. This high degree of plasticity of the Salivaria also supports the idea that these are relatively more recent parasites of terrestrial mammals than the Stercoraria.

As I have indicated, anterior and posterior-station developments of trypanosomes in tsetse flies and reduviid bugs are possible; so the site of multiplication and development of a trypanosome to the infective stage may not be dependent on the vector. If, however, the Salivaria originated recently from a leech–aquatic–vertebrate stock, they might have retained an anterior-station development after becoming adapted to arthropods for transmission.

Anterior-station trypanosomes of mammals have only been found in the tropics—for example, *T. vivax*, *T. congolense*, and *T. brucei* in tropical Africa and *T. rangeli* in tropical South America. Reptiles abound in the tropics and crocodilians are confined largely to the tropics. Lindsey[38] reported 677 species of reptiles (lizards and turtles) from the tropics compared with about 150 species in each of the warm temperate and cool temperate regions. Also most trypanosomes of reptiles seem to be confined to the tropics. Of the forty-three nominal species described from reptiles, thirty-eight have been described from animals collected from the tropics whereas only five are from hosts collected in the temperate regions. Daytime temperatures in many parts of the tropics can be high for long periods: the afternoon temperatures at Bolobo in the Congo, for example, range from 30°–34° C (85°–93° F) throughout the year[39]. Trypanosomes of reptiles in the tropics would therefore have to be able to withstand relatively high temperatures. This is especially true when reptiles are basking in the sun. Conceivably, some trypanosomes of these reptiles were able to survive and multiply in the blood of warm-blooded animals.

Initial transmission could have been through the bites of infected leeches when mammals come down to the river to drink; the trypanosomes may then have lived in the blood, and later transmission to other mammals could have been taken over by tsetse flies and other blood-sucking arthropods. Alternatively, the infected reptile may have been fed on by blood-sucking arthropods while on land. It is known that tsetse flies of the *palpalis* group, vectors of the Salivaria in Africa, feed on reptiles, especially crocodiles[40–42]. Trypanosomes may at first have been transmitted mechanically but later acquired a cyclical development in the vector[4,5,9].

Adler and Theodor[22] have demonstrated that sand flies, *Phlebotomus parroti*, can transmit *Trypanosoma platydactyli* which developed in forty of forty-three sand flies that had fed on infected geckos. The flagellates adopted an anterior position in the cardia and had progressed to the oesophagus within the first four days. Flagellates were not seen in the hind gut. Possibly *T. platydactyli* was originally a leech-transmitted parasite of an aquatic ancestor of the gecko, and evolved with this ancestral reptile as it colonized land retaining the anterior-station as its site of development when sand flies became involved in the terrestrial life cycle.

As I have pointed out, the Salivaria are morphologically distinct from other mammalian trypanosomes in that their posterior ends are rounded. But they resemble in size and form some of the trypanosomes described from reptiles in Africa, for example, *T. sebae*, *T. psammophis*[43] and *T. mochli*[44].

Red-eared turtles (*Pseudemys scripta elegans*) have been infected with *T. brucei*[45]. These turtles from temperate regions had to be acclimated to 35°–37° C for a month before infection was possible. Control turtles at room temperature (20°–22° C) could not be infected. In experimentally infected turtles the trypanosomes divided in the blood during the first six days. The infection persisted for at least 12 days after which the turtles were killed. The trypanosomes were still infective and pathogenic when inoculated back into mice.

Caimans (*Caiman sclerops*), normally found in tropical South America, can be infected with *T. brucei* without prior temperature acclimation[46]. The trypanosomes isolated from these caimans after 12 weeks were still infective and pathogenic when reinoculated into mice. Apparently *T. brucei* is not pathogenic to caimans, for the experimental animals were active and seemed healthy even months after infection. This may indicate an ancestral relationship between reptiles and this species of trypanosomes.

T. cruzi can also infect reptiles[47,48] but, as I have pointed out, *T. cruzi* is somewhat different from most members of the Stercoraria in that it is unusually pathogenic and has a wide host range. I am therefore inclined, with Baker[8], to feel that its origin may also be different from that of other Stercoraria.

Neolithic Trade Routes re-aligned by Oxygen Isotope Analyses

by

NICHOLAS SHACKLETON
Sub-department of Quaternary Research, University of Cambridge

COLIN RENFREW
Department of Ancient History, University of Sheffield

Oxygen isotope analyses of *Spondylus* shells from neolithic sites suggest that the source for the shells used as ornaments in the Balkans and central Europe during the fourth millennium BC was the Aegean and not the Black Sea. The trade in *Spondylus* may have taken the form of an exchange of gifts.

THE distribution in the European neolithic objects, chiefly beads and bangles, made from the marine bivalve *Spondylus gaederopus* Linne gives a clear indication of a prehistoric trade in this attractive material. Clearly, either the ornaments or the unworked shells must have been transported by man from the sea where the animal lives. Recent work on other materials, supposedly traded from the Aegean region to the Balkans and central Europe, notably obsidian and faience, has suggested that prehistoric contacts between these areas were fewer than had been previously supposed. This finding seems to strengthen the possibility that the source for the *Spondylus* used in the Balkans and central Europe was not the Aegean but the Black Sea; several authors have postulated its availability there in neolithic times[1,2]. We report here preliminary investigations into the characterization of the source of *Spondylus* shell through the analysis of the oxygen isotopic composition of the calcium carbonate of which it is constituted. Our results suggest the exclusion of the Black Sea as a source, and document the earliest known trading contacts between the Aegean and central Europe, in the fourth millennium BC.

The physical principle which we are utilizing in this study is that a mollusc deposits the calcium carbonate of its shell in isotopic equilibrium with the water it inhabits. That is to say, the proportion of oxygen-18 atoms to oxygen-16 atoms is governed by thermodynamical principles rather than by biological factors. In fact, the ratio of the two isotopes differs from that in the parent water by only a small amount, the extent varying slightly with temperature. From a geological point of view this is of interest because it is sometimes possible to estimate palaeotemperatures through an analysis of the oxygen isotopic composition of a fossil shell[3]. From our point of view, it means that shells from two different sources may be differentiated clearly, either if the source regions have markedly different temperature regimes, or if they are characterized by watermasses of substantially different isotopic composition. Although we are not aware of any previous attempt to use the technique in this way, the idea was suggested some years ago by Keith *et al.*[4].

Isotopic Compositions of the Black Sea and the Mediterranean

In the initial stages of the project, we decided to restrict ourselves to differentiating between *Spondylus* from the Black Sea and from the Mediterranean. Here we are relying not on a climatic difference, but on a considerable difference in the isotopic composition of the waters.

The mechanism responsible for the fact that not all natural waters display the same $^{18}O/^{16}O$ ratio is a relatively simple one. Because water molecules containing ^{18}O are heavier than those containing ^{16}O, they have a slightly lower chance of evaporating into the atmosphere, so that water vapour in the air, and rain water, are slightly depleted in ^{18}O (ref. 5). The differences are small, and

are expressed as a deviation in parts per thousand from an arbitrary standard using the δ-notation:

$$\delta = 1{,}000\left\{\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right\}$$

where R is the ratio of ^{18}O to ^{16}O in sample and standard as indicated. All values quoted in this article are referred to the Pee Dee Belemmite standard[6]. In the oceans, the observed variations are very small except in regions where evaporation is high, leading to a high salinity and a positive δ-value in the surface waters, and in regions where the admixture of fresh water reduces salinity and gives rise to a negative δ-value[6]. Several analyses have been published for Mediterranean water, which comes into the former category, in the range +1·1 parts per thousand to +1·3 parts per thousand[6–8], these referring to water with a salinity of about 38·5 parts per thousand. (The values cited in references 7 and 8 have been converted from standard mean ocean water isotopic standard (SMOW) to PDB standard; see ref. 9.)

The Black Sea is largely isolated from the Mediterranean; the water budget given by Sverdrup *et al.*[10] is: precipitation, 7,600; runoff, 10,400; inflow from Mediterranean, 6,100; evaporation, 11,500; outflow to Mediterranean, 12,600 (all figures in m^3/s). A comparison with the Caspian, where inflow is balanced by evaporation, suggests that the Black Sea would be expected to be isotopically slightly more negative; Longinelli and Craig give a value of −2·4 parts per thousand for the Caspian[7] so that we might expect a value between −2·5 parts per thousand and −3 parts per thousand for the Black Sea. Very recently an even more negative value, −4·15 parts per thousand, has been published[8]. In any event there is clearly a substantial difference between its isotopic composition and that of the Mediterranean.

The second factor upon which the isotopic composition of shell carbonate depends is temperature, a factor whose importance was demonstrated by Urey[11]. The scale of the variation may be indicated by the fact that a seasonal change from 12° to 25° C would give rise to an isotopic variation through the shell of about 3 parts per thousand if growth continued throughout the year. Carbonate analyses are again expressed as δ-values in terms of the PDB standard. The generally used relationship between isotopic composition and temperature is[12]

$$T = 16{\cdot}5 - 4{\cdot}3(\delta_c - \delta_w) + 0{\cdot}14(\delta_c - \delta_w)^2$$

where δ_c and δ_w refer to carbonate and water respectively. The standard deviation among replicate analyses of carbonate is generally about 0·1 parts per thousand representing about ½° C.

Isotopic Analyses of *Spondylus* Shells from Neolithic Sites

The samples we have analysed are from settlement sites, datable between 4,000 BC and 2,500 BC in radiocarbon years. Tell Goljanio Delschevo[12] is in the Varna district, near the Black Sea coast of Bulgaria; samples from this site (submitted by the excavator, Dr H. Vajsová Simeonová) were selected in view of the likelihood that they would, if the Black Sea were used at all as a source for the material, be from this source rather than from the much more distant Aegean. Sitagroi is a prehistoric settlement mound near Drama in Northern Greece, lying some 40 km from the Aegean sea coast (excavations here were jointly organized by C. R. and Professor Marija Gimbutas; specimens from phase III occupation of site were selected and sampled by N. S. with permission from the Greek Archaeological Service). Gradeshnitsa in north-west Bulgaria and Vinča[15] near Belgrade in Jugoslavia are both more than 200 km from the sea (specimens from the surface of the Gradeshnitsa site were collected in 1966 with the collaboration of the excavator, Dr Bogdan Nikolov; the Vinča specimens were selected from the collection in the University of Belgrade by permission of the curator, Mme Z. Letica). The results of the analyses are given in Table 1.

Table 1. CARBONATE ANALYSES

Site and sample No.	$\delta^{18}O$ (parts per thousand)	$\delta^{13}O$ (parts per thousand)
Tell Goljanio Delschevo 3	−1·06	+0·21
Tell Goljanio Delschevo 5	+0·04	+1·14
Tell Goljanio Delschevo 6	−0·71	+0·29
Sitagroi 548	−0·27	+1·16
Sitagroi 817	−0·97	+0·50
Sitagroi 896	−0·55	+0·52
Sitagroi 1,446	−0·17	+0·87
Gradeshnitsa	−1·21	−0·04
Vinča	−0·91	+1·19

It is immediately clear that the analyses fall into a single group; the samples from the site near Varna on the Black Sea coast would be consistent with temperatures between about 24° to 19° C in water of isotopic composition +0·6 parts per thousand. A more positive water would imply a higher maximum temperature; the value chosen is a plausible summer value. If, on the other hand, our samples were by chance biased in favour of winter fragments, they would be consistent with temperatures between about 17° and 12° C in a water with isotopic composition −1 part per thousand. Thus even in the unlikely event of our having sampled fragments deposited in winter, the implied isotopic composition for the water is not nearly negative enough to be consistent with a Black Sea origin for the fragments found at Tell Goljanio Delschevo.

Analyses of Recent Shells

Because this conclusion was rather surprising, we carried out analyses of some recent shells from the Black Sea (specimens were supplied by Dr M. Demir, Marine Laboratory, Plymouth), which, in fact, confirmed our earlier findings. Three shells were analysed sequentially so as to obtain the maximum range of growth temperature (Fig. 1). The overall range is satisfactorily large; if 24° C is used as a likely value for the maximum represented, the minimum would be about 10° C and the

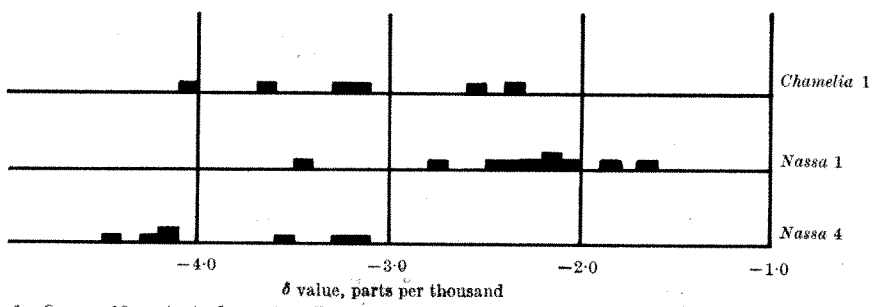

Fig. 1. Oxygen-18 content of recent shells from the Black Sea. *Nassa* 1 and 4 are *Nassa* (*Hinea*) *reticulata* L., collected at a depth of 79 m at 41° 26′ 35″ N, 29° 09′ E. *Chamelia* 1 is *Chamelia gallina* (L.) collected at a depth of 33 m at 41° 17′ 15″ N, 28° 53′ E. Each analysis is of about 0·25 mg shell sampled with a fine file; samples were taken so as to cover as much of the growth season as possible.

water isotopic composition about −2·6 per thousand, in satisfactory agreement with the value estimated. There is not any overlap at all with the values in Table 1. It is also of some significance that there is almost no overlap in carbon isotopic composition, the Black Sea samples giving δ-values for carbon of +0·28 parts per thousand to −3·77 parts per thousand (twenty-nine analyses). The factors governing carbon isotopic composition are complex[3], but from the almost total separation it seems certain that the *Spondylus* from Tell Goljanio Delschevo are, indeed, of Aegean rather than Black Sea origin.

There are two further points which must be considered before our conclusion is finalized. First, it is necessary to know that the samples analysed do, in fact, represent original carbonate, rather than the product of a later recrystallization. Carbonate undergoes isotopic exchange with groundwater if it does recrystallize; this is fortunate in our case because it means that although marine shell might give the impression of having derived from the Black Sea if some exchange with isotopically light groundwater had taken place, the reverse is not possible.

Second, it is pertinent to ask whether the Black Sea could have had an isotopic composition closer to that of the Mediterranean a few thousand years ago. The answer is that, if anything, it would have been more negative, because up to about 8,000 years ago the Black Sea was largely filled with glacial meltwater and was isolated from the Mediterranean owing to the glacio-eustatic lowering of sea level[13,14].

The extent to which our approach is capable of refinement is obviously complicated by the fact that the isotope ratio we measure depends on both the temperature and the isotopic composition of the water where the shells lived. Fortunately, however, only the first of these changes appreciably through the year (at least this is so away from river mouths). Although the objects analysed are often not large enough for many consecutive growth elements to be analysed, as the shells we chose from the modern Black Sea were, a number of small samples taken at random from several different shells is likely to represent a reasonable coverage of the growth season. Ideally, the analyses should cover a range wide enough to represent the maximum temperature range likely to have been experienced. If this were achieved, the isotopic composition of the water could be deduced within narrow limits; this in turn should narrow down the number of likely sources. In the case of the samples from Tell Goljanio Delschevo, the three analyses represent a range of about 5 degrees C. Because it is unlikely that the shell grew below about 12° C or above about 24° C, the water probably had an isotopic composition between −1·0 parts per thousand and +0·6 parts per thousand. This already suggests an Aegean source rather than, for instance, trade from a Cycladic Island. We are hopeful that, at least in some circumstances, we may be able to specify the likely sources of *Spondylus* from a critical site more precisely by analysing a greater number of samples.

Archaeological Implications

The conclusion that the *Spondylus* ornaments from Tell Goljanio Delschevo are of Aegean rather than Black Sea origin is at first a surprising one, because such ornaments are common in Bulgaria and Rumania from the time of the Hamangia culture[15] around 4,000 BC in radiocarbon years to the end of the Copper Age Gumelnitsa culture around 2,800 BC. We now plan to analyse samples from other sites near the Black Sea coast, in order to test the validity of the generalization that all the Balkan *Spondylus* is of Aegean origin. The analyses from Gradeshnitsa and Vinča, supporting those of Tell Goljanio Delschevo, strongly suggest this to be the case.

Recent finds at Sitagroi, in the north Aegean region, have yielded, in levels of phase III, pottery which is unmistakably of Balkan Gumelnitsa type. It is precisely in these levels that "bracelets" of *Spondylus* are most common, being rare in levels of the preceding phase II and absent in those of phase I. Finds of *Spondylus* are very common at this and other sites of the fourth millennium BC in the Plain of Drama, notably more so than at other sites in north Greece[16] or elsewhere in the Aegean[17], where the animal itself is abundant. The Aegean coasts near the Plain of Drama now seem the most likely source for much of the Balkan *Spondylus*.

Ornaments of the shell are particularly numerous in graves of the fourth millennium Linearbandkeramik culture of central Europe[18]. We hope to investigate further the differentiation between the Aegean and the Adriatic as possible sources for this material. Already, however, an early, long-distance trade with the Aegean is documented in the Balkans by finds of surprising number.

Definitive elucidation of the trading mechanism must await further study. Yet already the demonstration of the Aegean origin of the material sets the whole question in a different light. Finds of *Spondylus* ornaments are numerous in eastern Bulgaria and Rumania, some of the sites actually lying very close to the shores of the Black Sea. The decreasing number of finds with distance from the source might have been interpreted as conforming very approximately to a straightforward down-the-line trading mechanism, of the kind which has been postulated for the obsidian trade in the Near East[19], had the Black Sea been the source of the material. With the Aegean now recognized as the source the situation is transformed, for the quantities found do not decrease exponentially with distance from the Aegean coast as such a model would predict; finds are at least as common in Bulgaria and Rumania as in north Greece.

A different model, prestige chain exchange, is here proposed for the Balkan *Spondylus* trade. It has four defining characteristics: (1) the transfer of prestige goods takes place, often between persons of high status, on a basis of balanced reciprocity[20]; (2) the prestige goods are frequently handed on in subsequent exchanges; (3) such goods are not expended or utilized in daily life; (4) they appear in the archaeological record either as a result of deliberate burial (generally with the dead) or through loss or accidental breakage. A feature of such trade is that the traded goods are distributed over considerable distances, occurring in places remote from the source in quantities as great as at findspots nearer to it. Such now seems to be the situation in south-east Europe.

The best known exchange mechanism of this kind of recent times is the kula trade of the Trobriand islanders of the western Pacific[21], a conventionalized gift exchange whose social significance far transcended the utilitarian or "economic" value of the gifts[22]. As perhaps in prehistoric Europe, the most prized objects were bracelets of marine shell, and bead necklaces, many of them cut from shells of the genus *Spondylus*.

Simultaneous Measurements of Clear Air Turbulence at the Tropopause by High-power Radar and Instrumented Aircraft

Large amplitude Kelvin–Helmholtz billows observed by radar at a height of almost 11 km are shown to have been associated with clear air turbulence which produced a vertical aircraft acceleration of 0·65*g*.

A RECENT article[1] has reviewed the principles of the detection of clear air turbulence (CAT) by radar. Briefly, radar detects the incoherent backscatter from inhomogeneities of refractive index in the atmosphere occurring on a scale of half the radar wavelength (the most commonly used wavelength for the detection of CAT is about 100 mm). In the upper troposphere the inhomogeneities are associated mainly with fluctuations of temperature, these fluctuations being associated with small scale turbulence generated by Kelvin–Helmholtz instability (KHI). The vertical extent of KHI may be anything from metres to hundreds of metres, but only that occurring on a large scale gives rise to turbulence hazardous to aircraft. For this reason, attention was concentrated in the earlier communication[1] on the use of radar to detect deep KHI. A case study was presented showing the evolution of Kelvin–Helmholtz billows with crest-trough amplitude 400 m, across which the vector wind change was as large as 16 m s^{-1}. It was suggested that the breaking of KH billows such as these was likely to give rise to intense CAT. It is necessary to obtain direct measurements by aircraft, however, to establish this conclusively. The purpose of this article is to present other radar observations of large amplitude KH billows in which simultaneous measurements have been obtained by an instrumented aircraft.

Combined radar-aircraft measurements of CAT have already been reported by Glover *et al.*[2], but these were concerned mainly with situations of light turbulence in which the amplitude of the KH billows was too small to be resolved by radar. Moreover their turbulence measurements were made subjectively using an uninstrumented aircraft. The data presented in this paper are believed to be the first observations of moderate CAT in which

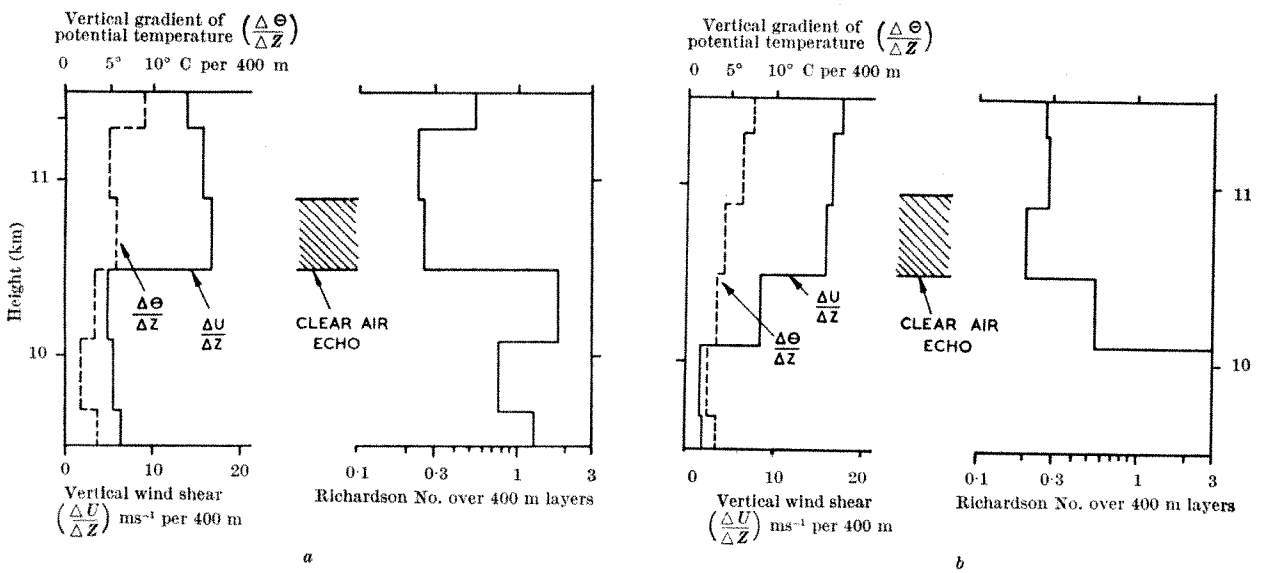

Fig. 1. Structure of the atmosphere in the vicinity of the tropopause on February 3, 1970, as derived from radiosondes released at Pershore at (*a*) 1243 GMT and (*b*) 1453 GMT. Each of the plotted parameters has been evaluated over layers 400 m deep.

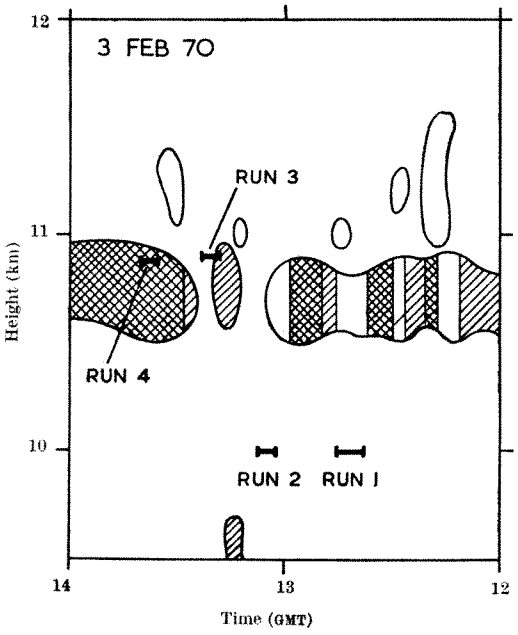

Fig. 2. Vertical extent of detectable clear air echoes associated with the KH billows on February 3, 1970, as a function of time. The horizontal extent of echo is represented by shading as follows: > 15 km (cross-hatched); 5–15 km (hatched); < 5 km (unshaded). Times and heights of aircraft runs are also indicated; registration between the radar and aircraft data is thought to have been closer than 1 min and 200 m respectively.

measurements by a fully instrumented aircraft are related to simultaneous radar observations of a specific patch of KH billows of known amplitude.

Observations of Clear Air Turbulence

The observations were made on February 3, 1970, while a strong upper tropospheric jet stream was overhead. The radar used in this study was the same one, at Defford, Worcestershire, that was described by Browning and Watkins[1]. It was operated to make 0°–90° elevation scans into the direction (280°) of the high level winds at a rate of roughly one scan every 3 min. KH billows were observed at tropopause level throughout almost the entire period of radar observations, from 1115 to 1530 GMT. The maximum range at which they were detectable was 50 km, and the amplitude of the billows (crest-trough) varied from less than 200 m to more than 500 m. (The amplitude may have been underestimated at times when the echo intensity was close to the threshold of detectability.) Vertical profiles of wind, temperature and humidity were obtained by means of radiosondes released at 2 h intervals from Pershore, Worcestershire. These showed that wind speeds reached 70 m s^{-1} from 280° beneath a tropopause which was situated between 10·5 and 10·9 km. Data from two of the radiosonde ascents are reproduced in Fig. 1 to show the structure of the atmosphere in the vicinity of the tropopause. The vertical extent of radar echo from KH billows is also indicated in Fig. 1, and it can be seen that the 400 m layer Richardson number Ri at the height of the billows was close to or less than 0·25 which, according to theoretical studies[3], is the critical value for the onset of KHI.

The aircraft was a Canberra from the Royal Aircraft Establishment, Bedford, fully instrumented for gust research studies. The instrumentation includes a wind vane mounted on a nose pole, a sensitive thermometer and an inertial platform[4]. The aircraft made ten almost straight and level runs at five different levels between 1240 and 1524 GMT along a line 170 km long from 52° 30′ N 04° 00′ W to 52° 00′ N 01° 45′ W. Each run was parallel (within ±10°) to the section scanned by the Defford radar, always remaining within ±7 km of this section when within radar range (5–50 km) and being within ±3 km during one of the more interesting runs (No. 4). The three highest flight levels, 11·8, 13·6 and 15·0 km, were entirely free of turbulence; no clear air radar echoes were detected from these levels. During parts of the flights at 10·0 and 10·9 km (runs 1–4), the aircraft encountered clear air turbulence within range of the Defford radar, and the remaining analysis consists of an interpretation of the radar observations in relation to the aircraft measurements at these two flight levels.

Fig. 2 depicts the height of runs 1–4 in relation to the vertical extent of radar echo associated with the KH billows. It shows that, whereas runs 1 and 2 were 500 m below the base of the principal layer of detectable echo, runs 3 and 4 were within this layer. The aircraft detected turbulence during only 14 per cent of runs 1 and 2 but continuously during runs 3 and 4. Fig. 3 shows that detectable billows occurred in a patchy manner, amplitudes greater than 300 m rarely being detected continuously for longer than 10 min or over distances greater than 20 km. Aircraft runs 3 and 4, plotted in Fig. 3, appear to have missed the billows of largest amplitude, although part of run 4 went close to a patch of billows with a maximum amplitude of 500 m. The aircraft accelero-

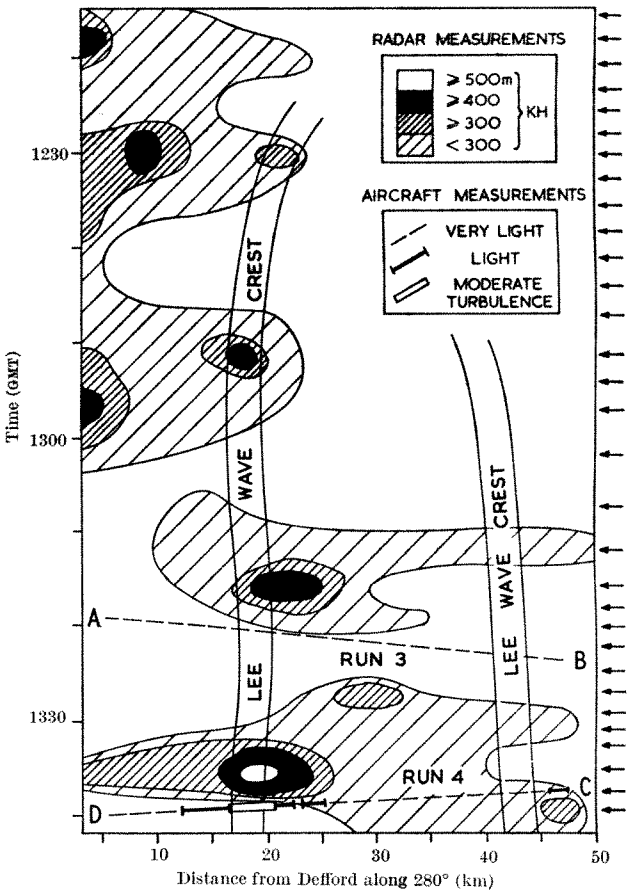

Fig. 3. Locations of detectable radar echoes associated with the KH billows at tropopause level, plotted in an x–t diagram, where t is time and x is distance from the Defford radar towards 280°. The crest–trough amplitude of the billows is indicated by shading (see key in diagram). Also shown are the positions of crests in the lee wave pattern as observed by radar. Arrows on right side of diagram denote times of individual RHI scans. The aircraft turbulence reports during runs 3 and 4 are plotted along AB and CD according to the code indicated in the key: very light, light, and moderate turbulence correspond to vertical accelerations of 0·1–0·2, 0·2–0·4, and 0·4–0·7g, respectively. Time and space registration between the radar and aircraft data is thought to have been closer than 1 min and 3 km.

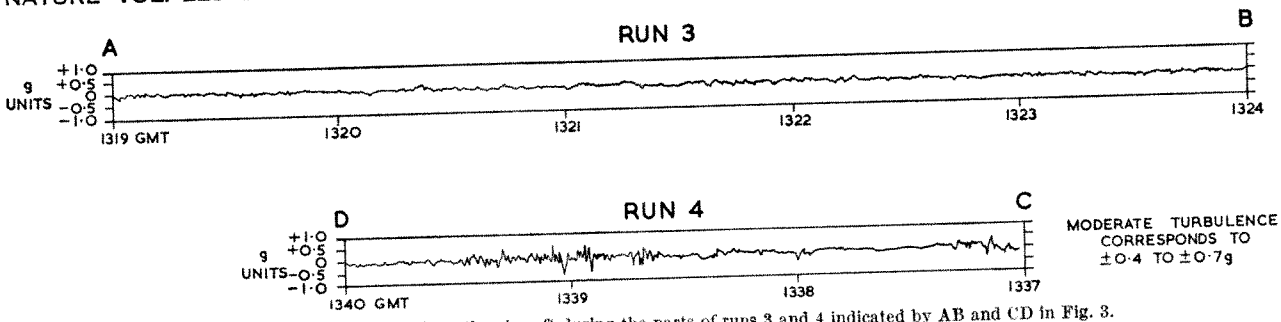

Fig. 4. Accelerometer traces from the aircraft during the parts of runs 3 and 4 indicated by AB and CD in Fig. 3.

meter traces for the parts of runs 3 and 4 labelled AB and CD in Fig. 3 are reproduced in Fig. 4. Perhaps the most striking feature of these records is that the maximum vertical acceleration of 0·65*g* (corresponding to moderate, almost severe, turbulence) occurred in close proximity to the patch of large amplitude billows observed by radar. This is not to imply, however, that the presence of large amplitude billows identifiable by radar is a sufficient condition for moderate CAT; it is also necessary that the billows should occur in association with very strong vertical wind shear. In this study, for example, there was a vector wind change of 17 m s^{-1} over a 400 m height interval.

Table 1. COMPARISON OF RADAR AND AIRCRAFT MEASUREMENTS OF BILLOW TURBULENCE AT TROPOPAUSE LEVEL MADE BETWEEN 5 AND 50 KM WEST OF DEFFORD DURING THE PERIOD 1320 TO 1340 GMT

	Radar measurements	Aircraft measurements (runs 3 and 4)
Height	Radar echo from billows at heights between 10·5 and 11·0 km	Aircraft flying at 10·9 km
Max. amplitude of billows (crest–trough)	500 m	220 m
Wavelength of billows	1 to 2 km	1·5 km
Percentage of range interval for which turbulence was detected	Radar echo from billows detected on average over about 50 per cent of 5–50 km range interval	Turbulence of at least very light intensity detected over 100 per cent of range interval. Turbulence of at least light intensity detected over 14 per cent of range interval
Principal turbulence event	One occurrence of billows with 500 m amplitude detected over a 3 km range interval	One occurrence of moderate turbulence detected over a 3 km range interval

A comparison of several aspects of the radar and aircraft measurements during runs 3 and 4 is presented in Table 1.

Although there is good agreement in the wavelength of the billows as measured by the two techniques, the agreement in amplitude is not as good. The amplitude and wavelength of the billows, as estimated from the radar data, have been obtained in a straightforward manner from the shape and dimensions of the echo. On the other hand, the amplitude and wavelength, as estimated from the aircraft data, have had to be obtained indirectly from the magnitude and periodicity of the fluctuations in potential temperature θ. The vertical excursions of air parcels have been estimated from the magnitude of fluctuations at a constant flight level, knowing the vertical gradient of potential temperature from the combined aircraft and radiosonde data. Although such a technique is reasonably valid for billows before they break, it will under-estimate their amplitude after they have broken owing to turbulent mixing. Probably the main reason for the aircraft giving a smaller amplitude than the radar, however, is that the aircraft narrowly missed the billows of largest amplitude.

The evidence in Table 1 and in Fig. 3 suggests that the radar detected all turbulence of at least light intensity encountered by the aircraft at 10·9 km. As noted earlier, however, the radar detected nothing at 10·0 km, corresponding to the aircraft flight level during runs 1 and 2. Although 86 per cent of runs 1 and 2 were indeed free of turbulence, the aircraft did encounter a small patch of light turbulence during run 2 which the radar failed to detect. The capability of the Defford radar for detecting CAT thus appears to be broadly consistent with the results of Glover *et al.*[2], who used a radar with a minimum detectable reflectivity of $1{\cdot}3 \times 10^{-15}$ m^{-1}, almost identical to that of the radar used in this work. They found that, for flights made at altitudes between 9 and 12 km, very light turbulence was detected by radar in 21 per cent of cases and light or moderate turbulence was detected in 41 per cent of cases. At lower altitudes the detection capability improves significantly.

Effect of Lee Waves

As is often the case when strong jet streams cross a barrier such as the Welsh mountains, lee waves of large amplitude occurred in the vicinity of Defford on this occasion. The lee waves were detected by the Defford radar as a result of the distortion of otherwise horizontally stratified echoes from the clear air (and also occasionally from cirrus). Because these layer echoes sometimes occurred simultaneously at several altitudes from 1·5 km to the tropopause, it was possible to determine the amplitude and wavelength of the lee waves as a function of height with a single radar scan taking only 3 min to complete. The wavelength was found to vary from 15 to 30 km. Crests and troughs were aligned vertically to within 1 or 2 km. The crest–trough amplitude of the lee waves was as large as 400 to 600 m at 2 to 4 km and, although the amplitude decreased above this, it was still as large as 100–300 m at tropopause level. According to Scorer[5], the development of KH billows is encouraged locally in parts of lee waves where isentropic surfaces are tilted appropriately, and similarly discouraged in other parts. This would partly account for the patchy nature of the distribution of KH billows shown in Fig. 3. Indeed, one might expect to find some overall relationship in Fig. 3 between the location of the billows with large amplitudes and the lee wave pattern. Pinpointing the regions of largest amplitude billows is made difficult by the range dependence of the echo intensity, and by the fact that the amplitude of the billows was underestimated at 10–15 km range because of the use of a moving target indicator radar system.

PHYSICAL SCIENCES

Separation of Matter and Antimatter

DOES the universe contain equal amounts of matter and antimatter? Unless one invokes an asymmetric initial condition, charge symmetry follows from the conservation of baryons. An asymmetric initial condition cannot be ruled out, however, and in fact is postulated in the standard version of the big-bang cosmology.

With the possible exception of cosmic ray statistics[1], observations yield essentially no information on the relative amounts of matter and antimatter beyond the solar system[2]. What the observations do tell us is that matter and antimatter are rarely, if ever, found together. Stringent upper limits on the amount of mixed matter and antimatter can be derived from dynamical arguments[3] and from gamma ray observations[4]. Even more conclusive is the existence of condensed objects, such as stars, each of which must be composed exclusively of either matter or antimatter. This high degree of separation cannot possibly be explained by statistical fluctuations[4,5]. It is therefore important from the standpoint of charge-symmetric cosmologies to explore possible physical mechanisms by which matter and antimatter can be separated. Several such mechanisms have been described by Alfvén (unpublished). One of these occurred to me independently and I think merits further attention.

Consider a gas of protons, antiprotons, electrons, and positrons which is sufficiently dilute that annihilation can be neglected. In general such a gas will be situated in a magnetic field $\mathbf{B}$, a gravitational field $\mathbf{g}$, and an electromagnetic-radiation field of flux $\mathbf{F}$. Each of these fields will be assumed static and homogeneous. In particular, the length scale for variations in $\mathbf{B}$ must be large enough that particle drifts arising from magnetic inhomogeneities are negligible.

The protons and antiprotons will usually be much more strongly influenced by the gravitational field than by the radiation field. As well as spiralling around the magnetic lines of force, the heavy particles will therefore have a drift velocity[6]

$$\mathbf{V}_h = \frac{m_p \mathbf{g} \times \mathbf{B}}{qB^2} \tag{1}$$

where m_p is the proton mass and q is the particle charge. Because of their smaller mass and larger scattering cross-section, the electrons and positrons will feel a much weaker gravitational force and a much stronger force due to radiation pressure. If the radiation force much exceeds the gravitational force, the drift velocity of the light particles will be

$$\mathbf{V}_l = \frac{\sigma \mathbf{F} \times \mathbf{B}}{qcB^2} \tag{2}$$

where σ is the Thomson cross-section of an electron (or an appropriate value of the Compton cross-section if the energy per photon is sufficiently high) and c is the speed of light.

As will be shown later there is a natural tendency in the universe for $\mathbf{g}$ and $\mathbf{F}$ to be antiparallel. When the radiation flux is sufficiently large for equation (2) to hold and when $\mathbf{g}$ and $\mathbf{F}$ are, in fact, antiparallel, it follows from equations (1) and (2) that protons and electrons will drift in one direction while antiprotons and positrons drift in the opposite direction; that is, matter and antimatter will tend to separate.

When B is measured in Gauss and the other quantities are measured in c.g.s. units, the magnitudes of the drift velocities (1) and (2) are

$$V_h \approx 10^{-4} \frac{g_\perp}{B} \tag{3}$$

and

$$V_l \approx 10^{-15} \frac{F_\perp}{B} \tag{4}$$

where the subscript $\perp$ specifies the vector component perpendicular to $\mathbf{B}$. It is clear from equations (3) and (4) that B must be very small if the separation mechanism just described is to have any cosmological significance. In this respect the mechanism contrasts sharply with Alfvén's electrolytic mechanism[2,7], which implies the existence of strong magnetic fields if significant amounts of matter and antimatter are separated.

It should be noted that, just as an electric current does not necessarily result in a separation of charge, the opposed drifts of matter and antimatter need not produce an actual matter–antimatter separation. The simplest example of a failure to separate would be an infinite matter–antimatter gas with $\mathbf{B}$, $\mathbf{g}$, and $\mathbf{F}$ uniform throughout. On the other hand, matter and antimatter in an isolated cloud or in an extended medium with an appropriate field configuration should achieve some degree of separation. Because the proton (antiproton) and electron (positron) fluxes will not be equal, in general, there will also be some separation of charge, leading to an electric field $\mathbf{E}$ and an $\mathbf{E} \times \mathbf{B}$ drift (which is the same for all particles). As the $\mathbf{E} \times \mathbf{B}$ drift increases, the heavy particles acquire an inertia drift which tends to remove the original difference between the proton (antiproton) and electron (positron) fluxes (unpublished work of Alfvén). Alfvén has pointed out that this fact makes separation possible even in the absence of an appreciable gravitational field.

There are two reasons why $\mathbf{g}$ and $\mathbf{F}$ may, in general, be expected to be antiparallel. The more obvious reason is that major sources of radiation are usually massive objects. Let us suppose that the gravitational and radiation fields originate at an object equivalent to a point source of mass M and luminosity L. The requirement that $\mathbf{g}$ and $\mathbf{F}$ be antiparallel is obviously satisfied. Matter and antimatter will tend to separate provided

$$10^{-11} < M/L < 0{\cdot}057 \tag{5}$$

where M and L are measured in solar units. The upper limit in expression (5) results from the requirement that the radiation force on each electron or positron exceeds the gravitational force; the lower limit follows from the condition that the gravitational force on the protons and antiprotons be greater than the radiation force.

Expression (5) is satisfied by supergiant stars and by main-sequence stars of types O and B. But stars obviously cannot be used to explain the initial stages, at least, of matter–antimatter separation in a charge-symmetric universe. Instead, we might appeal to objects deriving their luminosity from annihilation. Alfvén and Elvius, among others, have suggested that quasi-stellar objects are such entities (ref. 8 and a paper at the IAU Symposium No. 44, Uppsala, 1970). Although very little information on the masses of these objects is available (see ref. 9), it is likely that they obey condition (5). For example, if a quasi-stellar object with $L \approx 10^{47}$ erg s^{-1} has a respectable galactic mass of 10^{11} solar masses, then $M/L \approx 4 \times 10^{-3}$ solar units.

Another possibility is provided by the cosmology of Alfvén and Klein[7]. According to this scheme, an initial contraction of the metagalaxy (containing equal amounts of matter and antimatter) resulting from its self-gravitation was turned into an expansion by the pressure of radiation produced by annihilation reactions. If we suppose that the proton–antiproton and electron–positron gases are effectively coupled by a magnetic field which does not otherwise affect the dynamics, we obtain the equation of motion adopted by Alfvén and Klein

$$N_p m_p \frac{\mathbf{du}}{dt} = N_p m_p \mathbf{g} + N_e \frac{\sigma \mathbf{F}}{c} \qquad (6)$$

in which $\mathbf{u}$ is the gas velocity, N_p is the number density of protons (or antiprotons), and N_e is the number density of electrons (or positrons). Equation (6) may be rewritten in the form

$$N_p m_p \mathbf{g}_{eff} = -N_e \frac{\sigma \mathbf{F}}{c} \qquad (7)$$

where

$$\mathbf{g}_{eff} = \mathbf{g} - \frac{\mathbf{du}}{dt}$$

is the effective value of the gravitational acceleration, which should replace $\mathbf{g}$ in equation (1). With this substitution, we see from equations (1), (2) and (7) that matter and antimatter drift in opposite directions and, moreover, that the flux of proton gyration centres perpendicular to the magnetic field is equal to the flux of electron gyration centres (and similarly for antiprotons and positrons). Although the gravitational and radiation fields in this case are metagalactic, the scale of the matter–antimatter separation is determined by the magnetic field and is likely to be much more local.

The second general case in which $\mathbf{g}$ and $\mathbf{F}$ are antiparallel does not involve radiation generation by the source of the gravitational field but relies on the (presumably) black-body radiation of the universe. This radiation is usually discussed in terms of the big-bang theory and may[10] or may not[4] be consistent with a charge-symmetric cosmology. Let us consider a gravitationally bound system which is not participating in the universal expansion. As pointed out by Peebles[11], the black-body radiation tends to flow out of such a system because the radiation density decreases as the universe expands. Thus there is a net radiation flux which is antiparallel to the gravitational field of the system as required for the operation of the separation mechanism.

I thank Drs H Alfvén, P. Goldreich, W. Gruber, D. Layzer and R. McCray for their comments.

Observations of High Velocities in H II Regions

SEVERAL investigators using a variety of optical instruments have indicated that small components of the ionized matter in H II regions are in a highly turbulent state[1–5]. In particular, Shcheglov[3], using a photographic, single etalon Fabry–Perot at Hα in a non-classical combination with a telescope, found small components with turbulence of up to 100 km s^{-1} in M17 (NGC 6618), M8 (NGC 6523), the Orion nebula (NGC 1976) and M16 (NGC 6611). With this instrument he effectively took photographs at three adjacent positions in wavelength through a tunable 0·7 Å filter of the whole of these nebulae. They changed shape at different wavelengths though this was only apparent with widely varying exposure times.

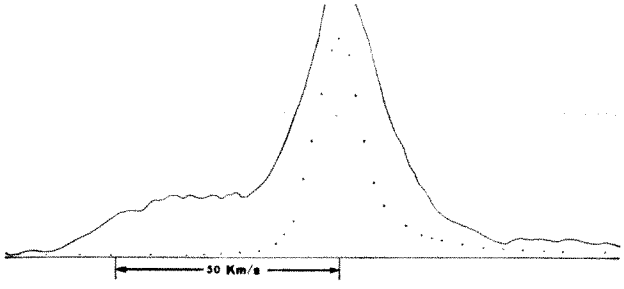

Fig. 1. The [O III] (5007 Å) line from a position in the centre of M16 is shown compared with the instrumental profile (dotted curve).

An exact measurement of the line shapes from the dense cores of several bright H II regions was desirable to reveal this turbulence and, if confirmed, to indicate its nature. For this it was necessary to reduce the ambiguities introduced by the single etalon Fabry–Perot but to retain its high potential luminosity–resolution product (L × R pot)[6]. I used a two etalon, propane scanned photoelectric Fabry–Perot, which has a high L × R pot, and a resolution of 0·2 Å but a very large free spectral range. A thermo-electrically cooled (−20° C) EMI 6256A photomultiplier was used as the detector. This spectrometer was combined classically with the 1 m reflecting telescope at the Pic-du-Midi observatory to convert its entrance cone into a smaller solid angle on the sky without significantly diminishing its L × R pot. The [O III] (5007 Å) line was chosen in preference to Hα because it is as bright, its thermal broadening is approximately four times less than Hα whereas the turbulent broadening, which is of interest here, remains unchanged, it is predominantly emitted by the dense cores of H II regions in the hardest radiation field of the exciting stars where any high velocity gas is expected to originate, and this line can be detected at three times the quantum efficiency of Hα. A 30 Å passband Fabry–Perot type filter was used to isolate the line.

Twenty-eight positions in the bright cores of three nebulae (M8, M16 and M17) in the Sagittarius arm were

observed with a 1′ beamwidth. The spectrometer and telescope combination was then being used well below L×R pot. Consequently, even extreme variations in brightness across the field of view could not significantly affect the shape of the profile.

The most remarkable scan of the 5007 Å line obtained from one position in the centre of M16 is shown in Fig. 1, together with the primary maximum of the instrumental profile. Clearly the line is split into two components; the faintest is being emitted by ionized matter approaching at 35 km s^{-1} with respect to the bulk of the nebular material. From other regions of M16, single though very broad lines (0·55 Å wide) are being emitted. The thermal width of the 5007 Å line at 10,000 K is only 0·1 Å.

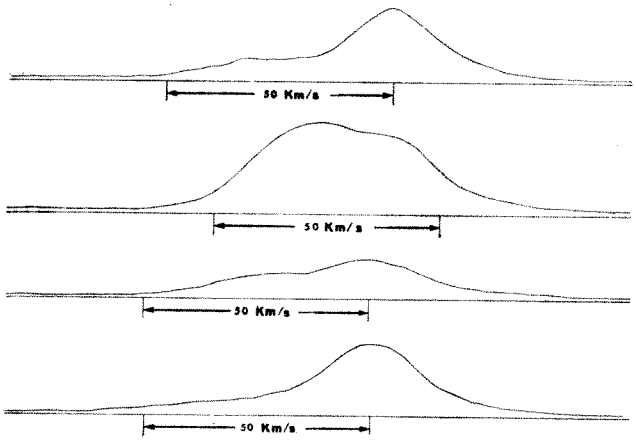

Fig. 2. The [O III] (5007 Å) line from four positions in the centre of M17.

In Fig. 2 the four most unusual scans that were obtained from four positions on M17 are shown. It is apparent that the nebular lines, that are convolved with the instrumental profile to give the scans that are presented here, must in some cases be strongly split and in other cases have turbulently broadened wings. Scans from many other positions in the core of this nebula indicate broad (around 0·3 Å) though more symmetrical lines. A very high signal to noise ratio (500 to 1) was achieved in the scan of the 5007 Å line from the region of M8 containing the 'Hourglass'. It is evident that the bulk of the matter is emitting an asymmetric 5007 Å line approximately 0·35 Å wide. The only other feature to produce a signal greater than 0·2% of this principal line within ±1·75 Å from it was a feature with 0·6% of the signal strength of the primary but 0·93 Å to its short wavelength side. This could be a 0·6% split component of the 5007 Å line being emitted by a small percentage of the matter approaching at 55 km s^{-1} with respect to the bulk of the nebular matter. But this feature is exactly on the level of uncertainty introduced by the partially transmitted [O III] line at 4959 Å. This will lie somewhere between 0·9 Å and 2·7 Å to the short side of the primary profile of the [O III] line at 5007 Å. Other possible sources of confusion for all these scans are negligible and need not be considered. These are the contributions from the He I (5016 Å) nebular line, airglow lines and Fabry–Perot ghosts. Only further observations will resolve the nature of this interesting feature on the scan of M8.

Here I communicate only the unambiguous confirmation and initial explanation of Gershberg and Shcheglov's[2,3] observations of M16 and M17. Some doubt still remains about M8 and no study of the Orion nebula has yet been carried out with this two etalon Fabry–Perot spectrometer. The physical interpretation of the exact deconvolution of all the irregular profiles will be reported elsewhere.

Photometric History of BL Lacertae

IN the discovery paper of BL Lac forty years ago, Hoffmeister[1] classified the object as a short-period variable with a range of m_{pg} of 13 to 15. Subsequent unpublished observations were made by van Schewick[2], and Semakin[3] observed a range of m_{pg} of 13·0 to 16·1 between 1950 and 1954. Schmitt[4] identified BL Lac with the radio source VRO 42.22.01, whose radio spectrum has been investigated by MacLoed and Andrew[5]. Optical and near infrared spectrophotometry by Visvanathan[6] and by Oke *et al.*[7] showed a steepening decline in flux density from 10^{14} to 10^{15} Hz. The nonthermal nature of the radiation and the optical variability resemble the characteristics of compact galaxies and quasistellar sources. Recently Tschäpe[8] re-examined the Sonneberg plate material and found a range of $m_{pg} = 12{\cdot}4$ to 16·1 during 1928 and early 1929. Modern photographic and photo-electric monitoring[9–12] showed that the variability of BL Lac is extremely irregular over periods of a few hundred days of continual observation. In view of the interest in the past variability of BL Lac expressed at the recent meeting of the International Astronomical Union, we present here photometric data derived from the archive plate collection of Harvard College Observatory. Our conclusions, based on the available BL Lac light history, are (1) the brightness of the object is fainter than 14 magnitudes most of the time; (2) the object has reached or exceeded magnitude 13 during two periods in its history; (3) during the second outburst, the brightness increased secularly throughout practically its entire range, and subsequently decreased again, the whole episode lasting about 10 years; and (4) there is a similarity in the optical behaviour of BL Lac and the N-galaxy 3C371.

We divided the Harvard plate material into two groups: (i) 114 plates taken with *f*/7 cameras of small aperture (3 inch) such as the RH and related patrol series; (ii) 51 plates taken with cameras of similar focal ratio but larger aperture (≥8 inch) such as the IR, MA, MC series. These 165 plates comprise all those available, excluding series with camera apertures < 3 inches and series in which BL Lac is confused with the image of the nearby star b in the comparison sequence of Bertaud *et al.*[9].

Fig. 1 summarizes the Harvard results as well as published data of other authors, and contains 60 Harvard data points of which 27 are determined by the Harvard Askania iris astrophotometer and 33 are based on visual estimates. The probable error of the iris-photometric points, as estimated from the scatter in plate calibration curves, is almost always ± ≤0·2 magnitudes. The visual estimates based on plates of group (ii) agree well with iris-photometric values in those cases where both exist. The visual estimates based on plates of group (i) are usually of poorer accuracy; the probable error can be as high as 0·5 magnitudes in the worst cases. Consequently,

although visual estimates have been made for all available Harvard plates, we have included in Fig. 1 only 12 group (i) visual estimates of special interest. The remaining available visual estimates, most of which merely conform to the trends shown in Fig. 1, have not been included pending iris-photometric evaluation. The photo-electric comparison sequences of Bertaud *et al.*[9] and of Kinman were used in our photometry. In view of the large brightness changes shown in Fig. 1, we consider it unnecessary to correct for the small differences in the photometric systems used by the various authors whose data are represented in Fig. 1 or for a small putative hour-angle effect[13] for nonthermal sources.

Fig. 1 reveals an interesting property of the light curve, that is, the brightness lies between magnitudes 14·0 and 16·6 most of the time but undergoes rare excursions to magnitude 13·0 or brighter. Only two such giant outbursts have been recorded. The first, observed by Tschäpe on Sonneberg plates, occurred over at least 400 days in 1928 and early 1929 during which the brightness increased to about 12·4 magnitudes with several rises and declines through almost the entire known range of variability[8]. The second was a much more prolonged and steady rise, again through almost the entire known range of variability, between 1950 and the late 1950s. This rise is documented by eight Semakin data points and fifteen visual and iris-photometric points from Harvard RH plates (group i) as well as by a visual estimate based on Palomar Sky Survey prints. The rise is shown in Fig. 2 on an expanded time scale. The Sonneberg data (open rectangles) and Sonneberg upper limits shown in Fig. 1, together with Harvard visual estimates not included in Fig. 1, also describe a subsequent decline in the later 1950s to fainter than magnitude 15·5 by the 1960s. Despite the comparatively large maximum probable error of the group (i) visual estimates ($\pm \leq 0{\cdot}5$ magnitudes), it can be reasonably inferred that BL Lac has undergone a long-term brightness increase and decline spanning 10 to 15 years. Inspection of our visual estimates of RH plates (group i) shows no other such giant outburst after 1930. Available Harvard material before 1928 is too scanty to decide whether outbursts occurred then.

The optical behaviour of BL Lac bears some resemblance to that of the N-galaxy 3C371 (ref. 14). This object

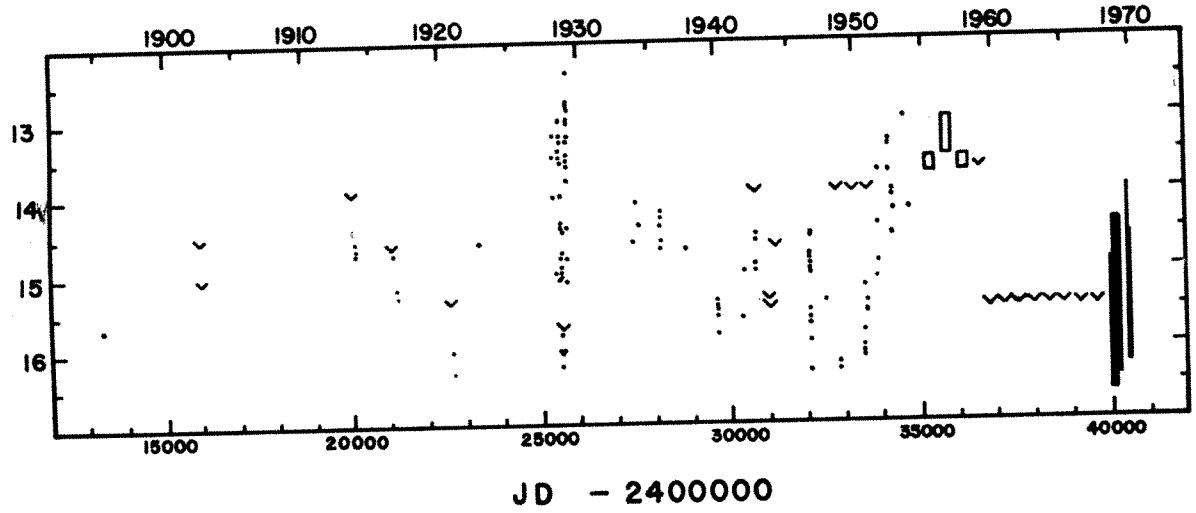

Fig. 1. Composite photometric history of BL Lac from 1895 to 1970. Axes are magnitudes (B or m_{pg}) and Julian days. The tip of a "V" denotes an upper limit in brightness. Filled rectangles enclose recent observations by various authors[9–12], open rectangles the data of Tschäpe[8]. All data in 1928 and all upper limits at 15·5 after 1958 are from Tschäpe. Eight points in the early 1950s are from Semakin[3] (see Fig. 2). The remaining points are from the Harvard plate collection. All upper limits brighter than magnitude 14 have been omitted.

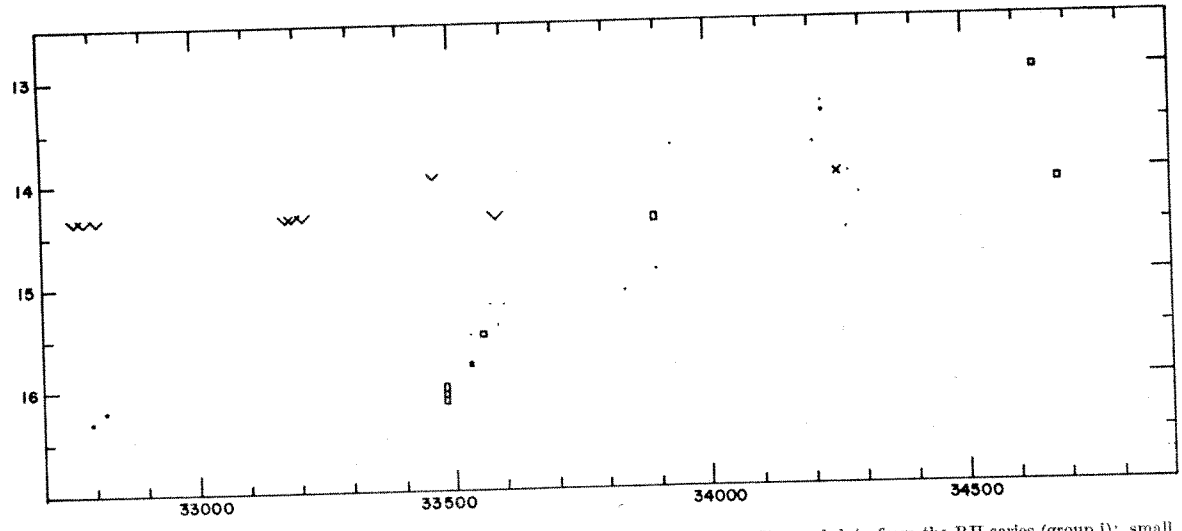

Fig. 2. A portion of the light curve of BL Lac on an expanded time scale. Dots are Harvard data from the RH series (group i); small dots are visual estimates, large dots iris-photometric values. Squares are Semakin's data. The cross is a visual estimate from the Palomar Sky Survey prints. Upper limits are indicated by "V". All upper limits brighter than magnitude 14 have been omitted. Axes are as in Fig. 1.

too has undergone a sustained outburst which lasted about fifteen years or more from 1895 to 1911. There is also scant evidence that a second outburst of 3C371 may have occurred fifty years later which lasted no more than ten years and which, like the 1928 outburst of BL Lac, was slightly brighter than the previous outburst. Kinman, Harlan and Marosan have pointed out still other similarities between BL Lac and 3C371. Terrell and Olsen[15] have shown that the light curve of 3C273 could be reproduced by a shot-noise simulation. It would be interesting to ascertain whether such a shot-noise model could also reproduce with reasonable probability the variations exhibited by BL Lac and 3C371.

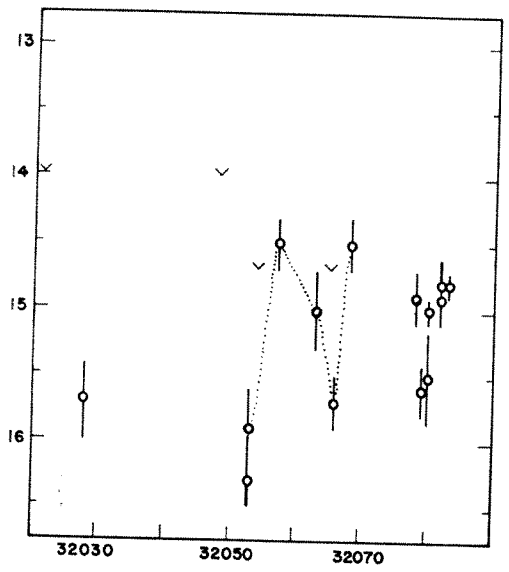

Fig. 3. A portion of the light curve BL Lac on an expanded scale. Upper limits are indicated by "V". All points and upper limits are derived from plates of the Harvard IR series (group ii). Axes are photographic *B* magnitudes and Julian days.

Fig. 3 shows another portion of Fig. 1 on an expanded scale. The dotted line indicates a brightening of some 1·5 magnitudes over four days (at a rate of 0·4 magnitudes per day) followed by a decline of 1·2 magnitudes over nine days (0·13 magnitudes per day) which is followed again by an abrupt return to the previous maximum value in two days (0·6 magnitudes per day). All these rates rely on single plates, but are consistent with the high rates found in modern observations[9–12]. One other well documented pulse, observed by Bertaud *et al.*[9] near JD 2440065, exhibits very similar properties; a brightening by almost 1 magnitude in three days followed by a decay over seven days to the original brightness. In both the case of Bertaud *et al.* and our case, the decay rate is about 0·13 magnitudes per day. It is interesting to recall that Type 1 supernovae show a comparable (0·1 magnitudes per day) decay rate near maximum. Multichannel-scanner observations of BL Lac have so far shown no obvious spectral features[6,7]. Because type I supernovae characteristically show line spectra a few days after maximum, it would be interesting to see whether spectral features could be detected in BL Lac near the end of an outburst of the kind shown in Fig. 3.

We thank the director and staff of Harvard College Observatory for permission to use the plate collection and auxiliary instrumentation and Bruce Hrivnak for technical help. Pulsar Ejection in Supernova Events

Although pulsar formation is generally attributed to supernova events, only two pulsars are associated convincingly with known supernova remnants (the Crab Nebula and Vela). Other pulsars are close enough to remnants to suggest association[1], but only if they are moving away from the remnant at velocities of the order of 10^3 km/s. Another problem seems to be that a supernova core may well be too massive to form a gravitationally stable object[2] (for example a "neutron star"), and gravitationally collapsing objects ("black holes") do not presently seem promising candidates to be pulsars.

Fowler and Hoyle[3] suggested some time ago that the symmetric ejection of radio-luminous material from galaxies could be caused by asymmetrical processes occurring in the collapse of very massive objects. Indeed, it is known that such an imploding system is Rayleigh–Taylor unstable. Thus the more massive core could fission into several less massive objects. The same idea can be applied to a supernova event, wherein the core fragments into some distribution of neutron stars, black holes and general debris (planetesimals, dust and so on). The number of fragments should be few, for the disparity between core mass and neutron star masses is not large. Such a multiple system would be readily detectable either directly as superimposed pulsars or indirectly from the orbital perturbations to the observed pulsar's period. At present, there is only a suggestion[4] that some pulsars have companions and then only of planetary mass.

Our point here is to show that the resultant system can be expected to become unbound, with the component objects (not all of which need be pulsars) ejected with velocities of the order of 10^3 km/s. Consider the binary fission of a supernova core into equal mass neutron stars. The collapse time to form two stars is expected to be of the same order as the time for the two stars to fall together. Furthermore, the conservation of the angular momentum of the original core would instead place them in highly excentric orbits as shown in Fig. 1. The semi-major axis would be comparable with the initial core radius, while the closest approach distance would be determined by the initial angular momentum of the core. Because final condensation occurs at the highest system

density, this will also be when the fragments are closest together.

At closest approach, the kinetic energy relative to the barycentre can be as high as a tenth of the rest mass (for "contact" trajectories), yet the system is only slightly bound. If now the rest mass of the system is rapidly reduced by a fraction f, the system would become unbound[4-7] by f times the gravitational binding energy less the total binding energy. The velocity at infinity would then be given from

$$V^2/c^2 = GM(2f-1+e)/2a \qquad (1)$$

where a is the closest approach distance to the barycentre, f is the mass loss fraction and e is the orbital eccentricity (nearly unity for the model described above). The eccentricity can be estimated roughly from

$$(1-e)/(1+e) \approx a/R_{\rm core} \geq R_{\rm pulsar}/R_{\rm core} \qquad (2)$$

which gives values for $1-e$ of about 5×10^{-3} for present supernova models. Escape velocities are thus obtained if $f \geq (1-e)/2$ or about $2{\cdot}5\times10^{-3}$. If nongravitational forces between the two fragments could be neglected, we would have

$$1-e = 2w_0^2 r_0^3/GM \qquad (3)$$

where w_0 is the initial rotation frequency of the core (radians/s) and r_0 is the initial distance between the centre of mass of each fragment-to-be and the total centre of mass ($r_0 \approx \frac{1}{2}R_{\rm core}$). Thus for one solar-mass object

$$1-e = 1{\cdot}8\times10^{-12}\, w_0^2\, R({\rm km})^3 \qquad (4)$$

and for nominal values ($w_0 = 0{\cdot}1$, $R = 10^3$), $1-e$ is even smaller than given in equation (2). Because nongravitational forces must act if the closest approach is less than the diameter of the neutron star, "contact" trajectories should be favoured. Note that relatively little energy is required to adjust the closest approach distance. The rest-mass energy fraction released in the neutron star formation event is perhaps of the order[8,9] of $f = 3\times10^{-2}$, which would give a recession velocity of 2×10^4 km/s for $a = 10$ km. The mechanism is less efficient if the energy is lost slowly, and a rough correction may be estimated from the replacement

$$f \rightarrow f^* \approx f(t_a/t_{\rm decay})^{2/3} (t_{\rm decay} > t_a) \qquad (5)$$

where

$$t_a^2 = a^3/GM(1+e) \qquad (6)$$

is the time for one radian of orbital motion at periapsis, and t decay is the characteristic time to release energy in the formation event.

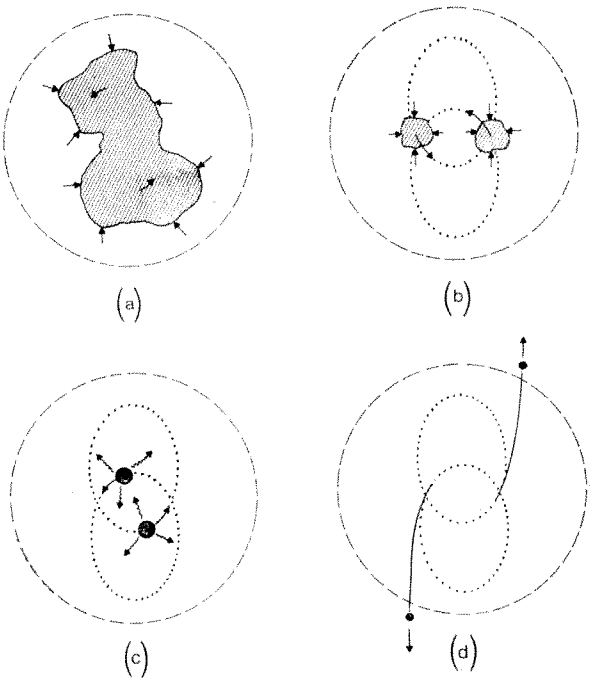

Fig. 1. Schematic development of run-away pulsars at the phases (*a*) collapse and fragmentation, (*b*) condensation, (*c*) radiation and (*d*) disruption. Dashed line shows boundary between ejected shell and collapsing core. Dotted lines show bound orbits after separation but before radiation. A complete orbit is not executed.

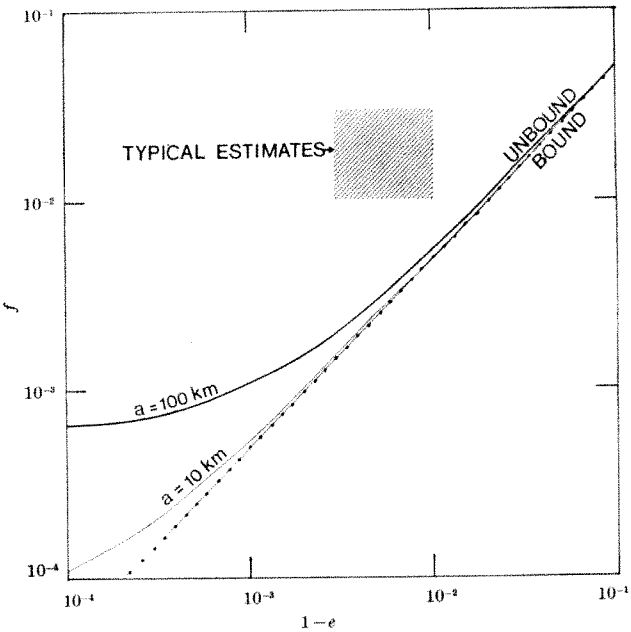

Fig. 2. Regions of f and e that permit disruption for various values of a assuming one solar mass pulsars. The mass-loss fraction f should be replaced by f^* if the emission is slow (see equation (5)). Above the solid lines for the appropriate value of a, the velocity exceeds 10^3 km/s, while below the dotted line, the system remains bound.

Fig. 2 shows the values of f, e and a required to produce runaway pulsars at a velocity in excess of 10^3 km/s. We see that nominal energy release values and stellar dimensions permit recession velocities of the order of or greater than 10^3 km/s. Similar ideas could be applied also to massive objects[3,7-9].

It is not clear from the available data whether such runaway motions are required for the pulsars. The absence of observed pulsars associated with the other supernova remnants could be attributed to the formation of non-pulsar objects (M. Rees, private communication) or of pulsars that are not beamed towards us. On the other hand, the mechanism proposed here seems capable of producing runaway pulsars whether they are yet required by the data or not. The detection of such objects would thereby be suggestive of fragmentation in the supernova event.

Absence of Average Polarization at 111·5 MHz in Pulsar NP 0532

THE average polarization properties of NP 0532 have been measured at about 400 MHz by us[1], by Manchester (private communication) and by Schonhardt[2]. Strong linear polarization is present in the precursor while the other pulse components are only weakly linearly polarized and the position angle is independent of pulse phase. The polarization properties of strong single pulses have been measured at high frequency by ourselves[3,4] and at lower frequencies by Staelin and Sutton[5], who have shown that large linear polarization does not occur in strong pulses. We have now measured the four Stokes parameters of the average pulse at 111·5 MHz.

The only difference in technique from our previous work was the use of a feed which yielded two orthogonal linear polarizations. The details of obtaining the Stokes parameters then differ slightly from our previous experiment in which two circular polarizations were provided by the feed. The four channels produced at baseband were passed through identical filters having a double-sideband width (to the 3 db points) of 5 kHz and were then digitized and recorded synchronously with the pulsar at 100 μs intervals throughout the entire pulsar period. We assumed the average intensity from the pulsar and the Crab Nebula itself to be unpolarized and used this as a calibration to eliminate instrumental polarization; thus the experiment was insensitive to time-independent linear polarization in the pulsar.

We carried out the observations for 3 h on both January 7 and January 11, 1970. The critical frequency of the ionosphere was measured at approximately 15 min intervals during the observations, using the ionosonde at Arecibo Observatory, and ionospheric Faraday rotation was calculated approximately using ionospheric density profiles supplied by G. Nelson.

Having accounted for rotation of the feed during tracking, we found that ionospheric Faraday rotation had rotated the position angle of linear polarization through about 140 degrees during each run. Each day's data were reduced in a series of short blocks accounting properly for Faraday rotation, and additionally in a series of short blocks in which the effects of Faraday rotation were ignored. In no case did we find appreciable linear or circular polarization. The present observations thus imply

$$P = \frac{\text{Peak-to-peak variation in } Q, U, \text{ or } V}{\text{Peak-to-peak variation in I}} \leq 0{\cdot}2 \quad (1)$$

The precursor pulse component at 430 MHz is essentially 100 per cent linearly polarized and is responsible for about 0·4 of the integrated (continuum equivalent) flux density. If the relative energies and polarization properties of the emitted pulse are similar at 111·5 MHz then the broadened observed pulse should exhibit more than 50 per cent linear polarization in the vicinity of the main pulse. Several explanations for the observed lack of polarization are plausible: the precursor may have become weak relative to the other pulse components at 111·5 MHz; it may not be strongly polarized on emission at the pulsar; or a strongly polarized precursor may have become depolarized in the medium in transit to Earth.

None of the above possibilities are subject to direct confirmation; however, Rankin *et al.*[6] have measured the integrated flux density of the precursor relative to the main pulse and found that the ratio is roughly independent of frequency in the interval 430 to 196·5 MHz. They argue that although the main pulse and precursor cannot be resolved at 111·5 MHz it is unlikely that their relative flux changes greatly in the octave between 196·5 and 111·5 MHz. In this case we may ask whether the depolarization is intrinsic to the source or occurs in the medium between Earth and the pulsar. Clearly, a strongly polarized precursor is severely broadened by scattering in the interstellar medium[6]; the scattering will not in itself change the fraction of linear polarization or its sense. But scattering introduces the possibility that differential Faraday rotation may occur on the various paths of propagation. We expect the scattering angle to be about 6×10^{-7} radians on the basis of the current knowledge of interstellar scintillation[6] and we believe it is unlikely that depolarization due to differential Faraday rotation occurs over such a small angular extent. (An observational indication of the importance of differential Faraday rotation at these low frequencies is provided by polarization measurements on quasars, which are observed to be linearly polarized at high frequency.)

Thus it seems most probable that either the pulsar's 111·5 MHz radiation is depolarized in the Crab Nebula, or in the immediate vicinity of the pulsar, or that the pulsar's radiation at low frequency is not strongly polarized on emission. A need for further polarization measurements of the Crab Nebula pulsar at intermediate frequencies is clearly implied.

We thank J. M. Comella and R. Dugatkin for assistance in developing the 111 MHz system, and J. M. Comella for use of his computer programs.

Battery Effect in Neutron Stars

RECENTLY there has been interest in the problem of intense magnetic fields in gravitationally collapsed bodies[1,2]; in particular the radio emission from neutron stars (pulsars) suggests strong magnetic fields of the order of 10^{12} G (refs. 1, 3 and 4). The battery effect for nonuniformly rotating early main sequence stars has been considered recently[5,6], but we will show in this communication that there is a possible battery effect in neutron stars which has a different physical cause.

Let us consider a rotating star which is composed only of neutrons, protons and electrons, and assume that they are completely degenerate. I have considered such a model of the neutron star and shown that the magnitude of the stationary magnetic field cannot be more than a few gauss. Here I shall show that there is a possibility that a non-stationary magnetic field of the order of 10^{12}G can be generated.

The effect of gravity will be considered using the post-Newtonian approximation. We assume that $\varphi/c^2 \ll 1$, so that only first order corrections in φ/c^2 to the Newtonian theory will be included in the basic equations of this problem. Then the space–time metric will be[3]

$$ds^2 = g_{ik}\, dx^i\, dx^k \quad (1)$$

where

$$g_{00} = 1 + \frac{2\varphi}{c^2}, \quad g_{\alpha\beta} = \left(1 - \frac{2\varphi}{c^2}\right)\delta_{\alpha\beta}$$

$$g_{0\alpha} = 0 \quad \alpha,\beta = 1,2,3$$

and where φ is the gravitational potential. If we denote **E** and **D** as the vectors of the electric field, and **H** and **B** as the vectors of the magnetic field, then Maxwell's equations have the form[8]

$$\text{div}\,\mathbf{D} = 4\pi e n_1 \quad (2a) \qquad \text{curl}\,\mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{B}}{\partial t} \quad (2d)$$

$$\text{div}\,\mathbf{B} = 0 \quad (2b) \qquad \text{curl}\,\mathbf{H} = \frac{4\pi}{c}\mathbf{S} + \frac{1}{c}\frac{\partial \mathbf{D}}{\partial t} \quad (2e)$$

$$\mathbf{D} = \frac{\mathbf{E}}{\sqrt{g_{00}}} \quad (2c) \qquad \mathbf{B} = \frac{\mathbf{H}}{\sqrt{g_{00}}} \quad (2f)$$

where en_1 and **S** are the densities of the electric charge and the electric current respectively. The macroscopic equation of motion for plasma in the space we are considering has the form[11]

$$\frac{\mathbf{S}\wedge\mathbf{B}}{cn_e} - \sqrt{g_{00}}\,\nabla P + mn(\nabla\varphi - \Omega^2\tau)\sqrt{g_{00}} = 0 \quad (3a)$$

$$\frac{\mathbf{S}}{\sigma} = \mathbf{E} + \frac{\mathbf{S}_p\wedge\mathbf{B}}{cn_e} + \frac{\sqrt{g_{00}}}{en_e}\nabla P_e - \frac{\mathbf{S}\wedge\mathbf{B}}{ecn_e} \quad (3b)$$

$$n_e = \alpha^{3/2} n \quad (3c)$$

$$\mathbf{S} = \mathbf{S}_p - \mathbf{S}_e = en_e(v_p - v_e), \quad v^\beta = \frac{dx^\beta}{dt} \quad (3d)$$

where τ is the distance from the axis of rotation, n is the density of neutrons, P is the pressure of neutrons, σ is the conductivity, $-e$ is the charge of the electrons, c is the velocity of light and v_p and v_e are the velocities of protons and electrons respectively. We assume that the density of electrons n_e is equal to the density of protons and the mass of the proton m equals the mass of the neutron. α is the ratio of the mass of the electron to the mass of the proton, and $1+\alpha$ is replaced by 1 since $\alpha \sim 5\times10^{-4}$. Equation (3) was obtained from the equation of hydrodynamic equilibrium written in its correct Einsteinian form[11].

If we take the curl from equation (3*b*), taking into account the fact that P is a function of n only and P_e of n_e only, and using equation (3*a*), then we have

$$\frac{\partial \mathbf{B}}{\partial t} = \frac{m}{e}c\Omega^2\frac{1}{c^2}\frac{\partial\varphi}{\partial R}\sin\theta\cdot\cos\theta\,\tau - c\,\text{curl}\frac{\mathbf{S}}{\sigma} - c\,\text{curl}\frac{\mathbf{S}\wedge\mathbf{B}}{cen_e} \quad (4)$$

where τ is a unit vector in the direction of the azimuthal angle φ. R, θ, φ are spherical coordinates. To obtain this equation we have used Maxwell's equation (2*d*) and the relations

$$\text{curl}\,\mathbf{E} = (\nabla\varphi - \Omega^2\tau)\wedge\nabla\sqrt{g_{00}}, \quad P_e = \alpha^{3/2}P$$

We assume that at the moment $t=0$ the star rotates like a solid body with angular velocity Ω. Then $\mathbf{v}_e^0 = \mathbf{v}_p^0$ and according to (3*d*) $\mathbf{S}=0$. The last two terms in equation (4) will vanish but the first term will be finite and thus a toroidal magnetic field is generated in the star. Provided that we include in the investigation the first order corrections of general relativity to the Newtonian theory, then we have the result that the effective angular velocity $\Omega(g_{00})^{1/4}$—where Ω is constant—depends on R. The electrons are driven relative to the protons, and the electric currents produced grow in time[5,6] and generate a toroidal magnetic field. The first term in equation (4), which describes the battery effect, is a constant in time, if Ω is a constant. But the next two terms (which have a tendency to stop the increase of the magnetic field) will grow because, according to Maxwell's equation

$$\mathbf{S} = \frac{c}{4\pi}\,\text{curl}\,\mathbf{B}$$

the electric currents **S** increase with the toroidal magnetic field. The length of time in which the Ohm term balances the battery term is $D^2\sigma/c^2$, where D is a magnitude commensurate with the radius of the star. The conductivity of a neutron star has been calculated[9] and was found to be of the order of 10^{29} s^{-1}. The length of time in which the Hall term becomes equal to the battery term is

$$\left(\frac{D^2\,en_e}{cA}\right)^{1/2}$$

where A is the speed at which the magnetic field increases and is given by

$$A \sim \left|\frac{m\Omega^2}{ec}R\cdot\frac{\partial\varphi}{\partial R}\right|$$

The speed at which the magnetic field increases depends on the central density of the matter of the neutron star. For a lower central density $\rho_c = 8\times10^{13}$ g cm^{-3} for which the mass is $M = 0{\cdot}12\ M_\odot$, the radius $R = 1{\cdot}2\times10^7$ cm, the maximal angular velocity $\Omega = 37$ s^{-1} and the average density of the electrons of the order of 10^{34} cm^{-3} (ref. 10). The speed of growth of the magnetic field is of the order of 10^{-4} G s^{-1}. For this model of the neutron star, the length of time in which the Ohm term balances the battery term is 10^{15} years, and the length of time in which the Hall term becomes equal to the battery term is of the order of 10^9 years. In order to find the magnitude of the maximum magnetic field, it can be assumed that on the time scale of the order of 10^9 years, the growth of the magnetic field depends linearly on time; this gives a field $\sim 10^{12}$ G.

For a higher central density $\rho_c = 5{\cdot}5\times10^{14}$ g cm^{-3}, for which the mass is $M = 0{\cdot}64\ M_\odot$, the radius $R = 10^6$ cm, the maximal angular velocity $\Omega = 6\times10^3$ s^{-1} and the average density of the electrons of the order of 10^{35} cm^{-3}, the speed of growth of the magnetic field is of the order of 3×10^2 G s^{-1}. The length of time in which the Ohm term balances the battery term is 10^{13} years, and the length of time in which the Hall term becomes equal to the battery term is only 10^5 years. This means that the maximum magnetic field is of the order of 10^{14} G.

The pulsar, which is known to exist in the Crab Nebula, has an age of the order of 10^3 years. If we identify this pulsar with the higher density model, and suppose that its angular velocity decreases linearly from 6×10^3 s^{-1} to 30 s^{-1}, then in 10^3 years the magnetic field can grow to $\sim 10^{12}$ G.

I thank Professor I. W. Roxburgh, Dr P. Strittmatter and Dr P. Eggleton for discussion and the British Council for support.

Comparison of Precise Radio Source Positions with Independent Optical Positions

In a recent letter[1], Wade *et al.* pointed out a systematic difference in right ascension between two independent surveys carried out at 2,695 MHz, one by the National Radio Astronomy Observatory, Green Bank, and the other by the Royal Radar Establishment, Great Malvern. The weighted mean difference in the sense NRAO minus RRE for 27 sources was $-0{\cdot}044$ s with a standard error in this mean of $\pm 0{\cdot}006$ s.

Each survey used essentially the same method to fix the scale in right ascension. The interferometer gave differential measurements to a high degree of accuracy, and the zero point was then fixed by comparison with astrometric positions for the optical counterparts of certain sources of small angular diameter. These optical positions were taken from various sources in the literature, and Wade *et al.* concluded that most of the discrepancy between the NRAO and RRE surveys must have arisen because of systematic differences between the various sets of astrometric measurements used by the two groups.

We have measured optical positions for thirteen sources in the RRE catalogue. We used the 43 cm classical Schmidt telescope at Cambridge. The reference frame was AGK 3 exclusively. It is legitimate to compare with the radio surveys because none of our measurements has been used in any of the calibrations. A comparison with RRE is set out in Table 1. 3C 9 is badly discordant and will be omitted from further discussion.

The mean difference Cambridge optical minus RRE in right ascension is $-0{\cdot}029$ s with a standard error in this mean of $\pm 0{\cdot}006$ s (Table 2). This difference is therefore highly significant, being five times its standard error. Comparing this with the difference NRAO minus RRE = $-0{\cdot}044$ s already quoted, we conclude that our optical measurements are somewhat closer to NRAO than to RRE as regards right ascension. In declination, on the other hand, there is no significant difference shown in Table 2 between us and RRE.

The RRE zero point in right ascension was fixed using 36 calibrators. The optical data were derived[1] from Griffin, from Veron, from Bolton and from Murray *et al.* Griffin's reference frame was the Yale zone catalogue except for declinations between $+30°$ and $+50°$ for which he used AGK 2. Veron used AGK 2 for declinations north of $-2°$, otherwise the Yale catalogue. Bolton used the Yale catalogue only. Murray *et al.*[2] used BD stars linked directly to FK 4 by transit observations, giving a system essentially equivalent to AGK 3. But since Murray *et al.* cannot have contributed more than 16 out of the total of 36 calibrators, it is clear that the RRE catalogue is tied mainly to a system based partly on the Yale catalogue and partly on AGK 2.

The NRAO survey used optical positions provided by Kristian and Sandage (unpublished). These authors measured with reference to an AGK framework for declinations north of $-2°$, and against the Smithsonian star catalogue southwards. At the time of writing, AGK 3 is available only north of declination $+10°$. Not having exact details it is impossible to make precise statements, but it seems that most sources in the Kristian and Sandage catalogue are tied to AGK 3, with a zone of intermediate declinations extending down to $-2°$ where measurements are tied to AGK 2 without proper motion updating, and finally a more southerly zone tied to the Smithsonian catalogue. Generally good agreement with our AGK 3 based measurements is therefore to be expected and has indeed been found.

Finally, we may note that the standard errors for one position difference in Table 2, namely $\pm 0{\cdot}022$ s in right ascension and $\pm 0{\cdot}28$ arc s in declination, are significantly lower than the corresponding values given by Wade *et al.*[1] for the differences between the two radio surveys, $\pm 0{\cdot}034$ s and $\pm 0{\cdot}50$ arc s respectively. These figures indicate that our optical measurements are of higher internal consistency than at least one of the radio catalogues. It would be inappropriate to discuss this in detail on the basis of the present limited series of optical observations, except to remark that it indicates that radio and optical astrometry are of comparable accuracy. If the structure of extra-galactic objects is to be investigated by intercomparing radio and optical configurations, then it is clear that a severe limitation may be imposed by inconsistencies between the radio and optical reference frames. Radio astronomers who rely on optical calibrations would have to exercise great care in the selection of optical data. Its reference frame would need to be self consistent over the sky to an accuracy of one or two-tenths of an arc s if the radio accuracy is to be fully

Table 1. RADIO AND OPTICAL SOURCE POSITIONS

0Q 208	14 h 04 m 45·65 s	45·63 s	−0·02 s	+28° 41′ 29·2″	29·1″	−0·1″
3C 345	16 h 41 m 17·64 s	17·61 s	−0·03 s	+39° 54′ 10·6″	10·8″	+0·2″
3C 380	18 h 28 m 13·54 s	13·51 s	−0·03 s	+48° 42′ 40·5″	40·5″	0·0″

Most of our results are based on three or four photographs. 3C 286 was so faint as to be satisfactory on only one. For six other sources the images were also either too faint or invisible, and we measured the "secondary reference stars" used by Murray *et al.*[2] from which we derived corrections to apply to the source positions given by these authors. These so-called "corrected" positions are given in brackets in Table 1.

Table 2. MEAN POSITION DIFFERENCES AND STANDARD ERRORS

	Right ascension	Declination
Mean difference (Cambridge optical—RRE)	$-0{\cdot}029$ s $\pm 0{\cdot}006$ s	$-0{\cdot}05″ \pm 0{\cdot}08″$
Standard error of one position difference	0·022 s	0·28″

utilized. It is not reasonable to expect regional variations in the reference frame to cancel out. This would require a sufficient number of local calibrators, and even if sufficient numbers could be measured accurately in the radio survey their optical measurement would in general need large telescopes and would only proceed slowly and laboriously.

We do not wish to propose here the adoption of any particular "system", but to emphasize that the time has now come for agreement to be reached between radio and optical workers.

We thank Dr C. A. Murray for furnishing finding charts and full details of the Herstmonceux measurements before publication, and Dr H. Gent for a pre-publication copy of the RRE catalogue.

Two Infrared Sources in Nebulae

In a systematic survey of the Caltech infrared catalogue (IRC)[1], 210 of the 5612 listed sources have been examined optically using the prints of the National Geographic Society–Palomar Observatory sky survey. Several criteria were adopted in the selection of sources for optical examination. Objects were first selected for which no previous identification was listed on the basis of comparison with star catalogues, and which further were very red as indicated by their I (0·84 μm) minus K (2·2 μm) colour index. The reddest sources among these have $(I-K) \geq 6^{m}\cdot00$ and all such cases were examined, whereas for the moderately red objects ($(I-K) \gtrsim 4^{m}\cdot00$) only sources at high galactic latitude ($|b^{II}| \geq 40°$), or lying in the $+40°$ declination zone of the two micron survey, or located near stellar rings[2], were inspected. During the work, a number of infrared stars of $(I-K) \gtrsim 4^{m}\cdot00$ but catalogued as belonging to spectral class B were also located. Examination of the sky survey prints revealed that the infrared object, in sixteen cases out of twenty investigated, was a fainter, very red star lying near the class B star in question. Some further named stars in the catalogue whose right ascension and declination offsets relative to the infrared source exceeded ~ 6 s and/or ~ 1′·2 were also examined, and again in nine cases out of fourteen a more satisfactory identification was made. On the basis of this admittedly small sample of stars with large offsets, it is suggested that such errors of identification may number about 100 stars throughout the catalogue, or about 2 per cent of the total.

Two particularly interesting sources coincided with small nebulae on the sky survey prints, and the main purpose of this letter is to give details of these. The first source is IRC+40091, with $(I-K) = 5^{m}\cdot72$, which has the position[1] (1950) 4 h 26 m 59 s ± 2 s, +35° 10′·2 ± 0′·3. This is identified with NGC 1579 which is a small, irregular, diffuse nebulosity, some 10 arc minutes across, with a prominent dark lane[3], and lies at[4] (1950) 4 h 26·9 m, +35° 11′. Pease[3] describes the brightest part of the nebula as a broad arrowhead; its appearance is very similar to that of the nebula about R Monocerotis. Very close to this cometary nebulosity, in the dark lane, is the faint star Lk Hα-101. Herbig[5] has discussed the source of illumination of the nebula, based on the unusual spectral features of the nebula and this star. He concludes[5] that Lk Hα-101 may be the exciting star if it is "very heavily obscured by dark material in the dark channel", and notes several spectral similarities between NGC 1579 and R Mon. The increasing brightness of the star through the photographic infrared to 2·2 μm seems strong evidence for this obscuration, and the brightness of R Mon at 5 μm, as reported by Low and Smith[6], makes NGC 1579 an object of great interest.

The second source closely associated with nebulosity is IRC+30407 with an $(I-K)$ index of $4^{m}\cdot48$, at[1] (1950) 19 h 59 m 55 s ± 2 s, +33° 22′·4 ± 0′·3. The position of NGC 6857, listed as a planetary nebula by Perek and Kohoutek[7], is (1950) 19 h 59 m 52·0 s, +33° 23′ 12″ and its extent is about 40 arc s. Four sources of radio emission have been detected in close proximity to NGC 685 by Wynn-Williams[8]. One is coincident with this nebula and a second has been shown by Higgs[9] to coincide with K3−50, a neighbouring nebula also listed as planetary. Both authors have interpreted the radio data as implying that these supposed planetary nebulae are in reality compact H II condensations excited by a cluster of OB stars. Elldér, Rönnang and Winnberg[10] have discovered an intense OH emission source at (1950) 19 h 59 m 51 s ± 15 s, +33° 25′ ± 3′, which is evidently associated with this region of nebulosity. It is unusual in that it is strongest in the 1720 MHz line whereas most infrared stars associated with OH emission are strongest in the 1612 MHz line, with little or no emission at 1720 MHz[11].

The recognition of an infrared source in this nebulosity strengthens the existing evidence from the radio observations that NGC 6857 is a region of active star formation.

We thank Dr G. Pooley and the staff of the University Computer Laboratory for the use of a source location program. One of us (M. C.) is supported by a grant from the Science Research Council. Our thanks also go to Professor R. O. Redman for helpful comment.

Strong New X-ray Object in the Cetus Region

In a recent flight of a Black Brant rocket, AKF-IIIB-51, we have observed a new intense source of X-radiation with a photon flux of 16·9 cm^{-2} s^{-1} in the 1·5–5·0 keV range. The rocket was launched on October 26, 1969, from Resolute Bay, Canada, at 0640 h GMT and reached an apogee of 196 km. It carried two proportional counters nested in a plastic scintillator mould, with their fields of view (~20° × 20°) in opposite radial directions. The detailed experimental configuration was similar to that used in earlier University of Calgary flights[1]. The detec-

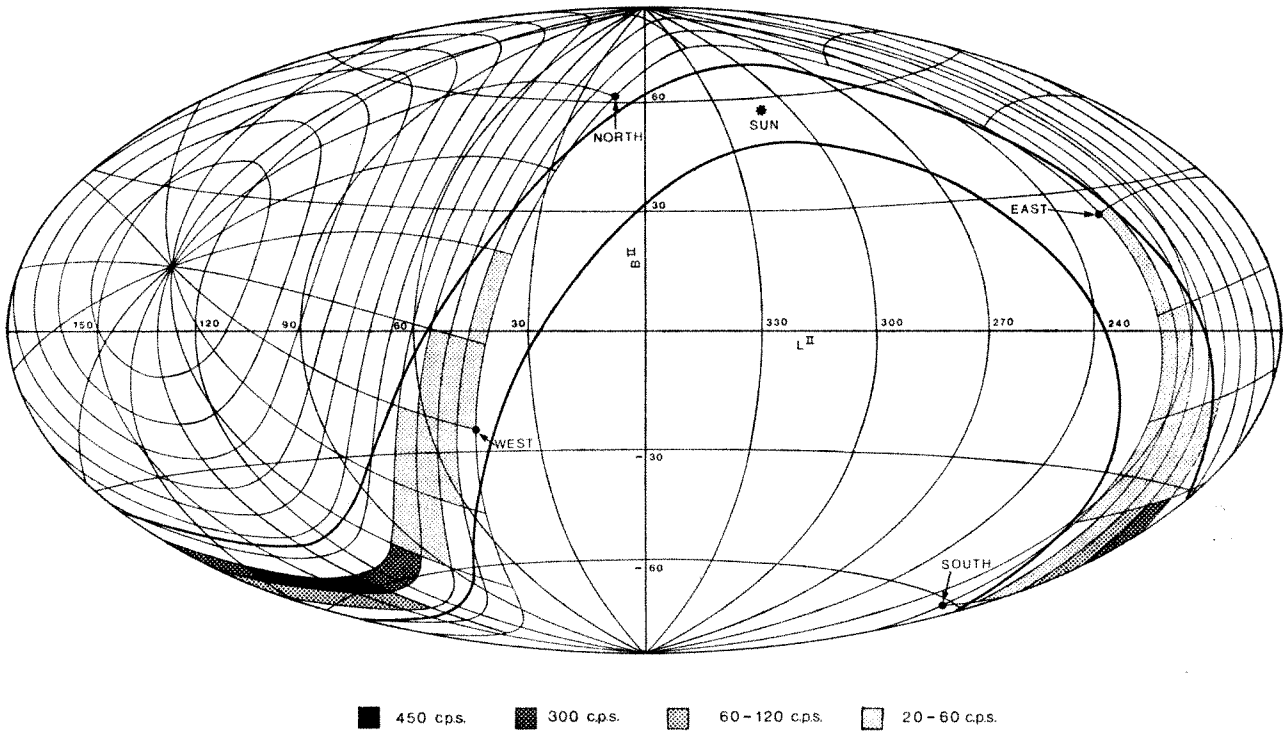

Fig. 1. Distribution of count rate in galactic coordinates (energy range 0·2–12·5 keV). Solid dark curves are the boundaries of the total area scanned. Unshaded region within the scanned area has either negligible scan time or the count rate attributed to detector background. Experimental horizon is defined by the curve with the north, west, south and east directions indicated on it by solid points.

tors had windows of $3{\cdot}0\times10^{-3}$ inch beryllium and $2{\cdot}5\times10^{-4}$ inch mylar so that together they covered the range of energies 0·2–12·5 keV. Above the atmosphere the rocket spun with a period of 3·34 s and precessed very slowly (period $\sim$52 min) about a cone of half angle 18°, consequently scanning almost the same region of sky on each sweep. The aspect was determined, using the data collected by three on-board magnetometers and a system of lunar sensors, to less than 2° uncertainty. At the time of the flight the Sun was 28° below the horizon with a shadow height of 750 km.

The general features of the flight are illustrated in Fig. 1. The count rate in the region of highest intensity was about six times the normal value. The data of the intense region were analysed separately after subtracting the contribution of both the diffuse X-radiation and the instrumental background.

Attempts were made to fit the data to the predictions of theoretical models of synchrotron emission, black body radiation and thermal Bremsstrahlung from a hot, thin plasma. The fit was poor with the first two models but was consistent with the third model giving the spectral distribution as

$$I=(20{\cdot}9\pm1{\cdot}0)\exp(-E/(7{\cdot}17\pm0{\cdot}57))\ \text{keV (keV cm}^2\ \text{s)}^{-1}$$

with the plasma temperature being $(8{\cdot}3\pm0{\cdot}7)\times10^7$ K. The fitted energy spectrum is presented in Fig. 2. Our estimate for the position of the object is $l^{II}=159°$ and $b^{II}=-52°$ (R.A. 2 h 14 min, dec. 4° 33′), the error circle being $\sim10°$.

Table 1 gives comparative figures for the energy and photon flux for a typical Sco-XR1 intensity[2] and the present object which we designate Cet-XR2. It is interesting to note that Cet-XR2 has an intensity comparable with that of Sco-XR1.

Table 1. CET-XR2 AND SCO-XR1 FLUX COMPARISON

Energy range (keV)	Photon flux (cm^{-2} s^{-1}) Cet-XR2	Sco-XR1	Energy flux (ergs cm^{-2} s^{-1}) Cet-XR2	Sco-XR1
1·5–5·0	16·9	25·9	$0{\cdot}7\times10^{-7}$	$1{\cdot}13\times10^{-7}$
1·5–10·0	22·3	32·9	$1{\cdot}35\times10^{-7}$	$1{\cdot}91\times10^{-7}$

A localized source in the Cetus region has been reported by Barnden and Francey (UAT group)[4] which has been designated as Cet-1 in the LRL catalogue[3] of X-ray sources. The position and intensities of Cet-XR1 and Cet-XR2 are summarized in Table 2.

The error circle estimated in the UAT experiment was approximately 15°. Within errors the two measurements could be referring to one and the same object. If this is so, the disparity in fluxes suggests that either the UAT measurement did not have a good geometry head-on view of the source or there has been a time variation in

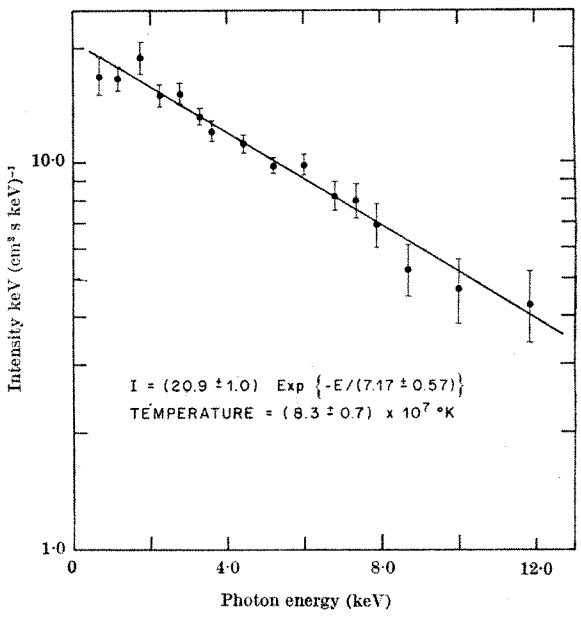

Fig. 2. Intensity of Cet-XR2 as a function of energy.

Table 2. COORDINATE AND FLUX DATA FOR CET-1 AND CET-2

	Cet-XR1	Cet-XR2
Galactic longitude (lII)	145°	159°
Galactic latitude (bII)	−60°	−52°
Intensity (photons cm^{-2} s^{-1} in the range 1·5–5·0 keV)	1·5	16·9
Date of observation	Dec. 1, 1967	Oct. 26, 1969

the intensity of the source, as has been observed, for example, for Centaurus-XR2, a nova-type object which has a similar exponential spectrum. The provisional location of Cetus-XR1 appears to have been very close to the experimental horizon so that the intensity of the source may have been underestimated.

On the other hand there may be two distinct sources in this region of the sky. The provisional location of Cetus-XR2 appears to be somewhat below the horizon of the UAT observation and consequently it would have been unobservable at the time of the earlier flight. Unfortunately neither of the two experiments yields sufficiently precise positional information to clarify the situation at the present time. Tentatively we consider that these are two different sources. Future experiments with more precise determination of the position should clarify the situation.

Nocturnal Variation of the Intensity and Rotational Temperature of the OH (8,3) Band in the Airglow

THE OH airglow is a sensitive indicator of conditions in the mesosphere. We report the results of measurements of the intensity and excitation temperature in the OH (8,3) vibrational rotational band, carried out with a spectrophotometer of simple design. Light entering a 3 mm diameter iris is collimated with a 170 mm focal length lens and impinges on a narrow band interference filter of 5 cm diameter; the filter has a bandwidth of approximately 3 Å and can be tilted to scan the band between 7300 Å and 7403 Å. The filtered light is detected with a cooled photomultiplier 'EMI 9558A (S20)'; photon counting is accomplished with a multichannel analyser 'Laben 100'. An entire scan, including dark current measurements, is carried out automatically in about 20 min. After removal of sky background and dark current the experimental spectra are compared with synthetic spectra obtained by considering the theoretical contribution of all lines of the OH (8,3) band under the assumption of thermal equilibrium. The χ^2 criterion is utilized to optimize the fitting; best values for the relative intensity and the rotational temperature are obtained at intervals of one hour every night. Observations reported here were carried out for a total of 22 nights and 276 scans during July to December 1969 and for a total of 7 nights and 72 scans during July to December 1968. Data were taken near l'Aquila (42° N, 13° E) at two locations: at Campo Imperatore (2,200 m above sea level) until August 1969 and at Preturo (700 m above sea level) after that date.

The graphs in Fig. 1 indicate the average variations of rotational temperature and intensity throughout the night, referred to the hour of sunset and to the local midnight. The graphs were obtained by considering, for each night, the difference in rotational temperature and relative intensity at successive hourly intervals. The intensity was referred to the minimum value obtained during each night. A decreasing trend during the night is evident for both intensity and temperature. The intensity variation is in reasonable agreement with estimates for the rate of emission of OH* obtained by Hesstvedt[1] with his photochemical model. The variation is probably because of the decrease in the OH* production rate associated with the decrease in the ozone and hydrogen concentrations at night near the mesopause. A decreasing trend with a slightly larger variation is found in the results of Shimazaki and Laird[2]. Hunt[3] also calculated the rate of formation of OH* and found a much larger nightly variation. His results, however, cannot be directly compared because they do not include quenching. In previous studies of the diurnal variation of the OH emission intensity[4] an overall fall of intensity from evening to morning was often present, but contamination by O_2 bands may have affected those earlier broad band measurements. Present measurements are thought to be relatively immune from contamination of other airglow emissions in view of their selectivity and the procedure used in reducing the data.

Measurements of intensity in general can be affected also by variations in atmospheric transparency. Measurements of rotational temperature are, in contrast, less sensitive to such possible cause of error. They are, however, difficult to interpret, because OH emission takes place at heights where radiative and collisional deactivation processes are competitive, and because rotational temperature may not reflect the ambient temperature. We point out that no systematic measurements of OH rotational temperature or of mesospheric kinetic temperature exist.

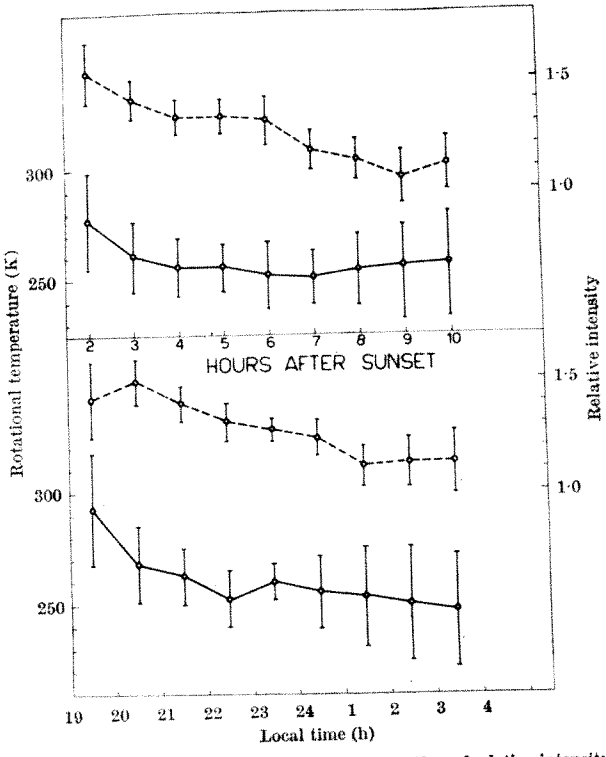

Fig. 1. The graphs indicate the nocturnal variation of relative intensity (- - - -) and rotational temperature (———) for the OH (8,3) band. Time variations are referred to local midnight and to the sunset.

A change in rotational temperature may thus reflect changes in the excitation process and in the height where the process takes place, as well as changes in ambient kinetic temperature. According to Hesstvedt's model, the change in intensity from sunset to midnight is accompanied by a change in the bottom height of the layer of only 1 km approximately. If the rotational temperature was constant this change could account for a measured variation of only a few degrees. The difference that we notice appears to be larger; if Hesstvedt's model is valid, it could point either to large variations in ambient temperature or to substantial differences between rotational temperature and ambient temperature.

Experiments are in preparation to observe simultaneously the kinetic temperature of OH lines and the rotational temperature of two OH bands.

Night-time Anomalies in Very Low Frequency Propagation produced by a Galactic X-ray Source at Centaurus

Night-time propagation of very low frequency (VLF) waves in the terrestrial ionosphere shows considerable variability, both in phase and in amplitude, in comparison with the relatively stable daytime conditions. The night-time anomalies are not yet well understood, a number of them being associated with the presence of energetic particles originating from solar proton events[1]. The explanation of others remains obscure.

It has been demonstrated, however, that the night-time ionization at heights around the upper boundary of the Earth–ionosphere waveguide, for VLF waves, may contain an appreciable contribution from the stronger celestial X-ray sources[2,3], and, indeed, long-term observations confirm the influence of the transits of Scorpius XR-1 and Taurus XR-1 on the amplitude of 164 kHz signals[4] and on the phase at frequencies below 30 kHz[3]. Calculations have shown, however, that the phase effects are indeed very small and that they can often be masked by large seasonal variations of other origin[3,5].

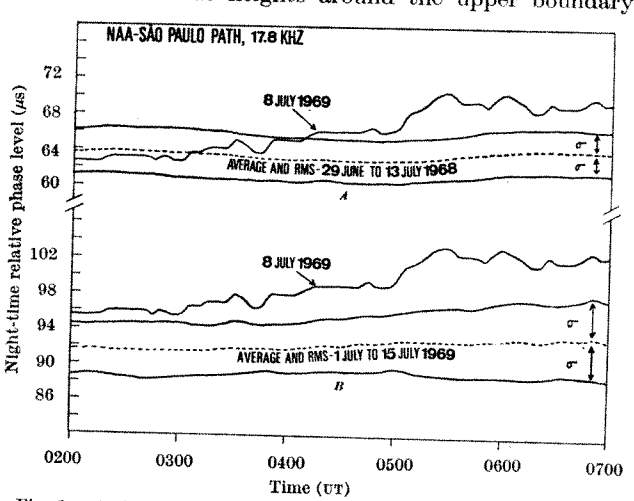

Fig. 1. *A*, The night-time phase anomaly recorded on July 8, 1969, compared with the mean value and standard deviation range for the fifteen days containing July 8, one year before, when the reported source was absent. *B*, The July 8, 1969, night phase compared with average values and σ range in the period July 1–15 of the same year.

The appearance of a very strong X-ray source in the southern sky, reported by Conner *et al.*[6], and observable between July 6 and 9, 1969, produced on July 8 a very clear night-time ionospheric disturbance on VLF transmissions from NAA (17·8 kHz, 7·4 mm path) received at São Paulo by a receiver controlled by a rubidium standard oscillator. One preliminary method to witness such an event is to compare night-time levels with the standard deviation range (σ) in a period of at least 15 days, containing the anomalous day. Fig. 1*A* shows the night phase record of July 8 together with the mean value and σ range in the period of June 29 to July 13, 1968. Night-time phase daily values were plotted around the mean value for the period of one year before fitting the averages in the interval 0200 to 0400 UT. In the period July 1–15, 1969, only the night-time phase from July 8 presented a significant departure from the σ, but some small deviations were also noticed, after 0400 UT, for July 5, 6, 7, 9 and 11. The reported Centaurus location[6] ($\alpha = 14$ h 56 m and $\delta = -32° 15'$) indicated that at that epoch the effect should be noticeable for nearly 8 h after sunset throughout the night.

A similar treatment was given to the period July 1–15, 1969, taking averages of 5 min intervals from 0200 to 0700 UT and establishing σ (corrected for the daily oscillator drift). Again, the night-time phase on July 8 presented a significant departure from σ throughout the night (Fig. 1*B*). A small deviation could also be seen on July 7.

Conner *et al.*[6] also reported that since the source discovery its spectra showed a daily softening. The rate of softening was irregular with no change in the period from July 16–18. The new source became stable after July 24, with flux and spectrum comparable with the neighbouring Scorpius SR-1, and was again observed on August 7 by Kitamura *et al.*[7]. On July 8 the X-ray hardness ratio between the 6–12 keV and 3–6 keV ranges was greater than one[6], and was enough to ionize the night-time upper boundary of the Earth–ionosphere waveguide for VLF waves—(85–90 km). There are at least two modes of propagation dominant[8] so that the observed phase retardation, $4 \lesssim \Delta\varphi \lesssim 6$ s, is the result of the relative changes of the first and second order modes and not a direct measurement of the reflexion height lowering, as is usually inferred from daytime SIDs. A more intense and persistent ionizing source would certainly produce a subsequent phase advance similar to that which occurs at sunrise.

In the following periods of July 17–31 and August 1–15, 1969, averages and r.m.s. ranges were taken. The phases from July 23 and 25, and August 7, were below the average through the whole night although the decrease was less than 2σ, an effect that could be caused by inaccuracies in the experimental determination of the drift. The night phase of July 30 and August 14 were above the average all the time, below or equal to 2σ. The whole period, from July 1 to August 15, 1969, was geomagnetically rather quiet, excepting July 26, when an SC was reported by ESSA, Solar Geophysical Data, apparently unrelated to the discussed anomalies. These results would suggest a possible recurrent activity, at least on the hardening of the celestial X-ray source spectrum, but the quality of the data, the lack of knowledge on the other possible causes for night-time anomalies, and the too small ionizing intensities, make it diffi-

cult to determine the sidereal dependence of the anomalies.

The effect on amplitude was much less evident, because of the even bigger variation of NAA signal level at night. On July 8, 1969, the attenuation effect after 0400 UT was less than 0·6 dB/mn.

In VLF data handling we usually assume a normal distribution of deviations. We tried different representations, deciding in favour of the one described. If we simply plot all the night-time phase records together, or peak-to-peak range, corrected for daily experimental drift, the July 8, 1969, record shows a clear departure from the others. In the periods of June 29–July 13, 1968, and July 1–15, 1969, only a few night-time phase records from the 1969 period exceed σ, but they are always below 2σ—as pointed out in the text. Taking 15 days phase data, departures as large as 2 to 3σ are not common.

In conclusion the anomaly produced by hard and intense galactic X-rays is more pronounced and definite than long-term effects, and the present result encourages a detailed search of other night-time anomalies which could be associated with the appearance of celestial X-ray sources and to the variability of others already known[3]. VLF data on long propagation paths, controlled by atomic frequency standards, are very suitable for that purpose.

We thank Dr F. H. Reder, who is director of the INT-VLF programme and provided us with computer facilities for VLF phase reductions, and we are grateful to Dr S. Ananthakrishnan for his useful comments on this paper. Aleutian Deep-sea Channel on the Aleutian Abyssal Plain

THE Aleutian abyssal plain is a vast turbidite deposit south of the Aleutian trench (Fig. 1). Hurley noted[1] that the plain had been cut off from turbidity currents as a result of the downbowing of the trench which had interrupted the turbidity current process along the bottom. In support of this thesis, seismic reflexion evidence[2] indicated an unusually thick layer of pelagic sediments overlying the turbidite layers on the Aleutian plain, and, using pelagic sedimentation rates, he placed the cessation of turbidity current activity in the early to middle Tertiary. The discovery of the Seamap channel[3], which is beheaded by the Aleutian trench, provided striking further evidence of the fossil nature of the Aleutian plain.

Another prominent channel trends south-westerly for more than 1,000 km across the abyssal plain (Fig. 2). This feature consists of a series of deltaic structures

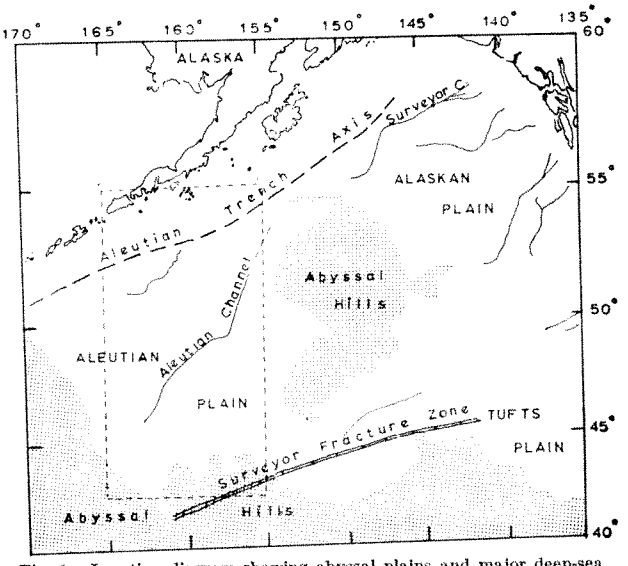

Fig. 1. Location diagram showing abyssal plains and major deep-sea channels in the north-east Pacific. Dashed line indicates area shown in detail as Fig. 2.

extending along its length. It is the largest single sedimentary feature on the Aleutian plain and is here named Aleutian channel. This unique deposit seems to occupy the axis of what was once a very broad south-west trending valley or elongate basin. This valley (basin) seems to have been a shadow zone to turbidity currents during an early stage of sedimentation in this region. This shadow zone coincides with the region where linear magnetic anomalies 25 to 32 (ref. 4) bend abruptly from a northerly to a westerly trend forming the Great Magnetic Bight[5], suggesting that during the initial stages of sedimentation turbidity currents were diverted away from the axis of the Bight by an associated topographic grain. A prominent topographic grain parallels these magnetic anomalies in the region immediately west of the Aleutian plain[6]. Remnants of the old shadow zone are now present in the form of two "secondary" shadow zones flanking the Aleutian channel. Although these flanking zones have undergone a certain amount of lateral filling they still show some of their original characteristics. Lateral filling has resulted in several enclosed basins (shown by depression contours in Fig. 2) that occur along the axes of both shadow zones. The largest basin lies within the eastern portion of the plain (Fig. 2). It apparently became an enclosed feature when a secondary channel, branching off Aleutian channel in a southerly direction, bridged the south-west trending shadow zone.

The Aleutian channel thus seems to represent one of the last stages in Aleutian plain turbidite sedimentation; the following is offered as a possible sequence of events leading to its formation. (In Fig. 2 deltaic units are assigned numbers 1 through 6.) Early turbidite sedimentation was controlled by the initial volcanic topography and a broad shadow zone trending north-easterly across the Aleutian plain remained. A point was reached when further inflow of sediment bridged obstructions to the north-east and found its way down the axis of the shadow zone, which now had become a receptacle for turbidity currents. Several local basin features—perhaps the result of differential sedimentation during the earlier stage—were located along the axis of the shadow zone. The initial inflow of sediment was primarily channelized, although various local depressions had to be filled in turn as the channel extended itself down the regional slope. Because the deltaic segments of Aleutian channel are best developed downstream from delta 2, this portion has been chosen for the discussion of their origin. A channel coming off of delta 2 found its way south of a pronounced east–west ridge (appearing now as two ridges, Fig. 2). Turbidity currents remained chan-

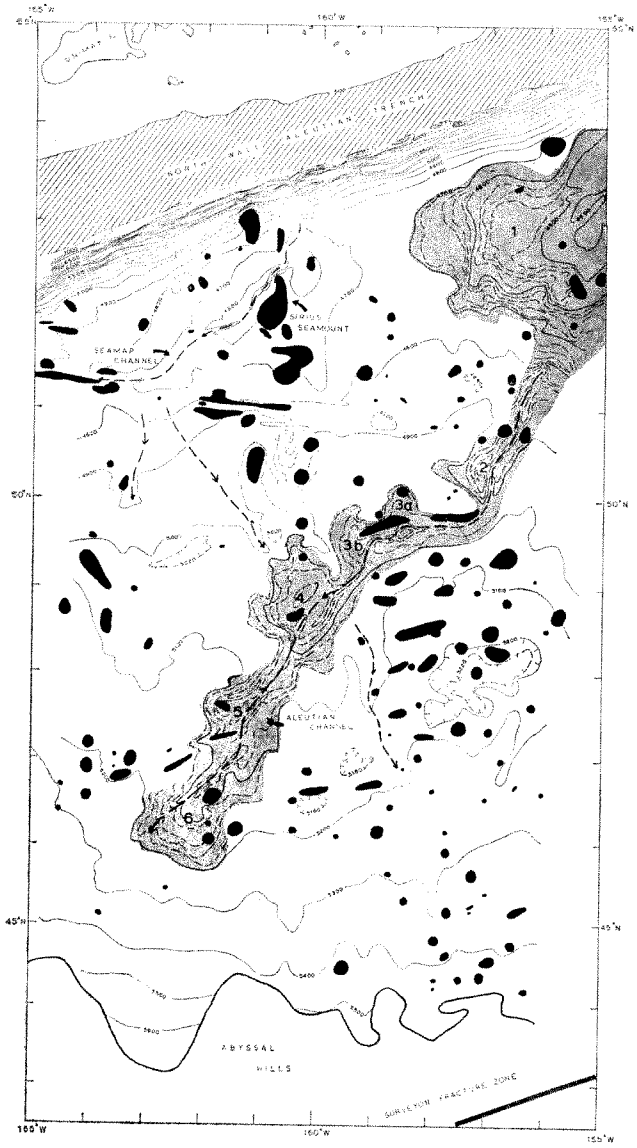

Fig. 2. Aleutian abyssal plain based on bathymetric data (north–south tracklines spaced at 10 nm (18·5 km) collected during ESSA's Seamap survey)[11]. The 100 m contour interval is shown by solid lines and selected 20 m contours are shown by light dashed lines. Aleutian channel deposit is shaded. Heavy dashed lines indicate channels. Black areas indicate volcanic topography as judged from an examination of fathograms.

nelized until they reached the western limit of the ridge, although a small amount of sediment apparently spilled over a low spot in the ridge at a later date and formed delta 3*a*. At this point the turbidity currents encountered a local depression and proceeded to fill it, primarily by means of sheet flow (or unchannelized turbidity currents). Sheet flow, radiating away from the point where the turbidity currents had lost their channel, continued until a small deltaic structure (delta 3*b*) occupied what was once a depression. When slope relationships made it possible for the channelized portion to extend itself farther down the regional slope, channelized flow broke away from the delta at its most downslope location. This process seems to have repeated to produce deltas 4, 5 and 6, with channelized flow always extending the feature from the downslope portion of the deltaic unit. Turbidity currents ceased before the principal channel had become aggraded to its slope, as is shown by the relatively steep slope in the channel axis at each location where the channel leaves a delta. Delta 1, although similar in morphology to the other deltas, is considerably larger and apparently represents a late-stage surge of sediment on to the Aleutian plain. This is based on the observation that the channelized portion of delta 2 ends abruptly on encountering delta 1 (Fig. 2), suggesting that its upstream portion has been overlapped.

It seems significant that the deltaic units of Aleutian channel are positioned on the right side of the channel (looking downstream). This bias may be purely the result of the initial topography coupled with a tendency of the principal channel to break away in a downstream direction; alternatively, it may reflect an influence of Coriolis force. The well documented asymmetrical levee heights of deep-sea channels[2,7] are clearly the result of Coriolis tilting of channelized turbidity currents; and the left hook of channels on mature abyssal plains (in the northern hemisphere), though somewhat more difficult to explain, also seems related to the Coriolis phenomenon[7]. The effect, if any, of Coriolis force on an unchannelized turbidity current is straightforward. Without confining levees turbidity currents would tend to turn toward the right in the northern hemisphere.

The source of the turbidity currents that deposited the Aleutian plain is difficult to determine because the upstream portion of the plain has been obliterated by the trench. The region of abyssal hills east of the Aleutian plain and immediately south of the trench (Fig. 1) precludes a present-day access to turbidity currents from the Alaskan plain which is a region of relatively recent turbidite deposition. It is possible that the Aleutian plain source lay north of the trench and that an ancient continuously sloping pathway from the continental margin of the Alaskan Peninsula was interrupted by downbowing of the trench, but recent views on sea-floor spreading favour an alternative explanation. By introducing a mobile sea-floor, a turbidity current pathway could have existed between the abyssal-hill region and the trench and subsequently migrated into the trench. In the New Global Tectonic model[8,9], the oceanic crust in this region is now moving north-westerly. Accordingly, the Aleutian plain may have been some 350 to 500 km south-east of its present location when its turbidity current supply was cut off[10]. The orientation of Aleutian channel and the turbidite morphology of the adjacent region strongly suggest that the source of sediment was immediately north of the abyssal-hill region. It is thus likely that the Aleutian plain is a distal portion of the Alaskan abyssal plain. This suggestion becomes increasingly more possible the farther south the crust is placed at the time turbidity current activity on the Aleutian plain ceased.

The relation between Aleutian channel and Surveyor channel (Fig. 1) suggests they were connected before the time the turbidity current pathway north of the abyssal-hill region migrated into the trench. If so, turbidity currents probably flowed through Surveyor channel and into the Aleutian trench, along a slightly diverted path, for a while after its distal segment (Aleutian channel) was severed by the trench.

Elemental Variations of Transport Coefficients Across Density Interfaces in Multiple-diffusive Systems

We report here laboratory measurements of the fluxes of several solutes across a density interface, between two fluid layers which are in a state of turbulent convection. Transport coefficients defined for the different components are shown to vary systematically with the molecular diffusivities, and it is suggested that this separation must be kept in mind when using the distribution of trace elements as an indicator of the mixing (of water with different salinities) in the ocean.

The instabilities which can arise in a fluid the density of which is affected by two components with different diffusivities are now well understood[1]. When the vertical density gradient of one component is stable, but the other is in the opposite sense and partly counteracts this, convective motions can be driven by the potential energy associated with the latter. Typically an initially smooth density distribution overturns in a series of steps, with well mixed convecting layers separated by sharper interfaces across which molecular processes are important[2]. The simplest example of the system of interest here is a warm salty layer of water underneath a cold fresh layer. Convection occurs in both layers because of the transfer of heat across the interface, while the more slowly diffusing salt preserves the density step across it. More generally, at such "diffusive" interfaces the substance with the higher molecular diffusivity is unstably distributed, and this drives a flux of the stable component between the convecting layers.

Quantitative laboratory experiments have been carried out[3] using heat and salt, and it has been found that over a wide range of conditions the ratio of the two fluxes is substantially constant. Preliminary experiments[2] using sugar and salt have shown that the fluxes must depend on the ratio of the diffusivities, but the process is still incompletely understood. In the work described here, we have attempted to answer a related but different question: what are the relative rates of transport across a "diffusive" interface between convecting layers when there are three or more components present, all with different diffusivities?

Three experiments have been conducted using different solutes and techniques; the initial conditions are summarized in Table 1. In the first, two 8 cm deep layers of tap water above a solution containing approximately 2 per cent sodium chloride and 1 per cent sucrose by weight were set up in a tank 30 cm in diameter and heated at a constant rate from below. Small samples were withdrawn from both layers at regular intervals, and the concentrations of salt and sugar were later deduced as functions of time. The basic measurements were of density (by weighing a 27 cm³ sinker in the sample), and sugar concentration (using a polarimeter with a 20 cm light path through the sample). Salt in the concentration present

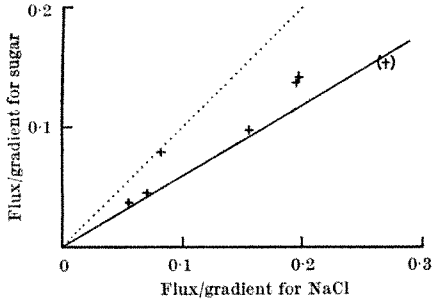

Fig. 1. Heating from below: the "transport coefficients" for sugar (the flux divided by the difference in concentration across the interface: see text) plotted against the corresponding values for NaCl. The scales are arbitrary, but the same for the two components; the relative values are directly as measured, except for the bracketed point whose coordinates have been halved for convenience of plotting.

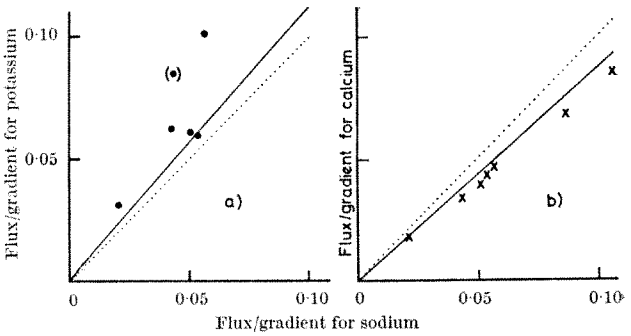

Fig. 2. As in Fig. 1, except that the transports of (*a*) potassium and (*b*) calcium are compared separately with sodium. The dotted line in these and other figures has unit slope, and the full line is drawn with a slope equal to the square root of the relevant diffusivity ratio (see Table 2).

made a negligible contribution to the optical rotation; the salt concentration was calculated as a difference, using a prior calibration.

The results are conveniently presented (Fig. 1) by defining "effective eddy transport coefficients" for sugar and salt, that is, the flux divided by a mean gradient. In terms of the concentrations of each property measured in the upper and lower layers at times t_0 and t_1 (say C_{u0}, C_{u2}; C_{l0}, C_{l1}), these may be written in difference form as

$$K \propto \frac{C_{u1} - C_{u0}}{\frac{1}{2}(C_{l0} + C_{l1}) - \frac{1}{2}(C_{u0} + C_{u1})}$$

The scales are arbitrary (for they depend on arbitrarily chosen time intervals and depths), but of course are the same for the two components so that a meaningful comparison is possible. The estimated errors are of the order of 15 per cent, but there is still clearly a systematic difference between the transports of sugar and salt, defined in this way.

The second experiment was carried out in just the same way, except that the heated lower layer now contained about 3 per cent by weight of NaCl, and a tenth of this concentration of KCl and $CaCl_2$. Analyses were carried out for the three metal ions by atomic absorption spectrometry, diluting the samples gravimetrically with distilled–deionized water to the appropriate concentration range, and aspirating them into a lean air–acetylene flame. A short path burner, mounted sideways, was used so as to minimize the amount of dilution required and to enable a wide range of concentrations to be accommodated on a single scale; calibrations were made directly using standard solutions. The results are shown in Fig. 2, where transport coefficients for both potassium and calcium are plotted relative to the sodium values. The potassium concentrations appear more variable than expected, possibly due to ionization in the flame; previous experience has shown the analytical error to be approximately ±4 per cent.

Finally, we give results from an experiment in which a layer containing 8 per cent NaCl and 0·4 per cent KCl was placed above a layer of more slowly diffusing sucrose (a 9 per cent solution). Again the interface is "diffusive", but there are now two components which can drive the convection, one much less concentrated than the other. The concentrations of sodium and potassium (but not sugar) were measured as functions of time using the atomic absorption technique. The timescale of this experiment was much longer than the previous two (a day instead of a few hours), but transport coefficients can be defined as before (Fig. 3).

Table 1. THE INITIAL PROPERTIES OF THE TWO LAYERS

	Exp. 1	Exp. 2	Exp. 3
Upper layer	Cold fresh water	Cold fresh water	8% NaCl, 0·4% KCl, 9% sucrose
Lower layer	2% NaCl, 1% sucrose. Heated	3% NaCl, 0·3% KCl, 0·3% $CaCl_2$. Heated	

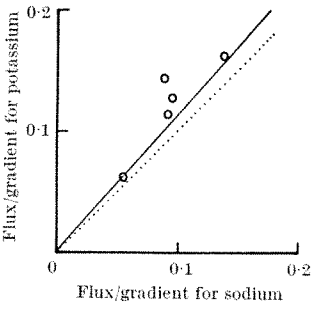

Fig. 3. Relative transports across a diffusive interface with NaCl and KCl above a sugar solution. See legend to Fig. 1.

In each of the three experiments a systematic molecular effect is evident when the transport of the various other components is compared with the rate for NaCl; the substance with higher diffusivity (KCl) goes faster and those with lower diffusivities (calcium and sugar) more slowly. The diffusivities used in making the comparisons are set out in Table 2 (taken from the *Handbook of Chemistry and Physics*). The values quoted are those appropriate for low concentrations, for it is difficult to evaluate absolute diffusivities in concentrated mixtures, but the ratios should remain roughly the same.

Table 2. DIFFUSIVITIES OF THE VARIOUS SOLUTES IN WATER AT 25° C AND LOW CONCENTRATIONS

Substance	KCl	NaCl	$CaCl_2$	Sucrose
Diffusivity $\varkappa$ (unit: 10^{-5} cm^2 s^{-1})	1·92	1·55	1·19	0·52
$\sqrt{\varkappa_x}/\sqrt{\varkappa_{Sa}}$	1·11	1·00	0·88	0·58

The only theoretical suggestion about the relative magnitude of the transports has come from the model of the mixing process described by Veronis[4] (for a two component system). He supposed that diffusive boundary layers form intermittently at the edge of the interfacial region before being swept away by the convection; this leads to a ratio of fluxes proportional to the square root of the diffusivity ratio. More work needs to be done to extend this argument to the present case, but nevertheless the full line on each figure has been drawn with this slope. In each case it is in fair agreement with the measurements, especially for the sugar–salt experiment (Fig. 1) which should be given most weight because of the greater diffusivity ratio.

Perhaps a transport rate increasing with the molecular diffusivity was only to be expected in this situation. We must remember, however, that the process described is largely a convective one, which operates because the large scale turbulent motions in the layers are continually sharpening the interface, and that the flux rates are much larger than can be accounted for by molecular diffusion through the mean gradient between the centres of the layers. If one sampled the motion and the concentrations without knowing that the interface existed, then one might say that the whole body of fluid was turbulent, with "eddy transport coefficients" which are different for the different components. Herein, we believe, lies the importance of the results when applied to oceanic processes. It does not seem permissible to assume, in the absence of a detailed knowledge of the transport mechanisms involved, that the "eddy diffusivity" deduced from the distribution of one component applies to another. Dissolved oxygen, for example, has a diffusivity comparable with that of KCl, and large molecular complexes will diffuse more slowly than NaCl. Because there is an increasing body of evidence that the typical distributions of temperature and salinity in the ocean are not smooth, but step-like[5,6], molecular diffusion near interfaces could certainly often be relevant.

Many other variants of this experiment remain to be explored, and it would clearly be desirable to measure all the transports simultaneously, not just selected pairs. We have not covered the whole range of relative concentrations of the components, though the behaviour of very small quantities of (radioactive) tracers, so small as to have a negligible effect on density, is of special interest. It would also be valuable to study systems of multiple layers, in which the observed differences could be enhanced by successive separations at several interfaces. Interfaces containing "salt fingers", which occur when the substance of lower diffusivity is unstably stratified[2], should be examined too; the experiments with two components suggest that in that case a higher molecular diffusivity will imply a relative reduction in the transport rate. There is the additional intriguing possibility of "mixed" interfaces, across which one pair of components will act so as to produce fingers, while another tends to make the interface sharp and "diffusive"; what actually happens then must depend strongly on the relative concentrations as well as the diffusivities. Our results using the simplest kind of interface do, however, indicate a need for caution when interpreting measurements of mixing rates in all multiple-diffusive systems.

Oceanographers have long been concerned with the simultaneous use of chemical tracers in oceanic studies. Broecker[7] has described a model to predict the observed distributions of ^{14}C, ^{226}Ra, ^{137}Cs, ^{90}Sr in the sea using one set of mixing conditions. Keeling and Bolin[8,9] have carried out a detailed examination of the use of box models, and pointed out that we lack direct evidence that the transfer coefficients behave as physical constants independent of the tracers under investigation. It may be that simple laboratory experiments such as we have described here can throw some light on the matter.

Adsorption of Hydroxy-aluminium Polymers by Muscovite and Biotite

THE wide occurrence of hydroxy-aluminium coatings on expansible phyllosilicate clays in soils and sediments has been extensively reported[1,2]. In view of the marked effects of hydroxy-aluminium coatings on many properties of clays, considerable efforts have been devoted to studying the process by which they are deposited on the interlayer surfaces of phyllosilicates, and to characterizing the hydroxy-aluminium interlayers formed both in nature and in the laboratory[1–11]. Little is known, however, about the extent of adsorption of hydroxy-aluminium polymers by the external surfaces of phyllosilicates. This article reports the adsorption of hydroxy-aluminium

Table 1. ADSORPTION OF HYDROXY-ALUMINIUM POLYMERS BY VARIOUS SIZE FRACTIONS OF MUSCOVITE AND BIOTITE

Size fraction (μ)	mg of Al adsorbed/g of mineral: Muscovite, Ratio of hydroxy-aluminium solution to mineral			Biotite, Ratio of hydroxy-aluminium solution to mineral		
	25 ml./g	50 ml./g	100 ml./g	25 ml./g	50 ml./g	100 ml./g
5–2	1·4	1·6	3·7	1·7	1·8	3·0
2–0·2	4·0	4·6	5·7	4·5	4·5	5·0
0·2–0·08	13·8	16·5	19·1	13·1	14·8	18·1
<0·08	13·6	28·4	37·9	13·8	28·3	38·9

Muscovite (Effingham township, Ontario, Canada) and biotite (Bancroft, Ontario, Canada) samples were broken into thin flakes and then wet ground in a Waring blender. They were then fractionated[13] and saturated with K by five washings with 1 M KCl. The excess chloride was removed by one washing with H_2O followed by four washings with 100 per cent methanol. The hydroxy-aluminium solution of OH/Al ratio 2·0 and of Al concentration 0·02 M was prepared and added to the minerals at a rate of 5 ml./min with continuous stirring. The freshly prepared suspensions, stored in flasks, were shaken in an end-over-end shaker for 30 min and then aged for two weeks at room temperature. After ageing, the suspensions were centrifuged and the supernatant saved for Al determination[13].

polymers by various size fractions of muscovite and biotite which have external surfaces only.

The amount of hydroxy-aluminium polymers adsorbed by the minerals increased as the ratio of hydroxy-aluminium solution to mineral was increased (Table 1). This can be explained on the basis of the principle of mass action. The adsorption of hydroxy-aluminium polymers by muscovite and biotite increased consistently with the decrease of particle size. Moreover, the amounts of aluminium adsorbed by the same size fractions of the two micas are comparable. At the ratio of 100 ml. of hydroxy-aluminium solution to 1 g of mineral, the amounts of aluminium adsorbed by the 5–2, 2–0·2, 0·2–0·08 and <0·08 μ fractions were around 3, 5, 19 and 38 mg/g of mineral, respectively. The <0·08 μ fractions of micas therefore adsorbed more than ten times as much hydroxy-aluminium as the 5–2 μ fractions. The increase in the adsorption with the decrease of particle size is attributed to the increase of external surfaces, for there are no interlayer spaces in the K-saturated mica particles. The X-ray diffraction data of the minerals before and after adsorption of hydroxy-aluminium polymers show the characteristic d spacings for micas. Raman and Mortland[14] reported that the external surface area of muscovite and biotite increased considerably with the increase of fineness of particles. They further stated that there was a reasonably close agreement between the calculated and the measured values for the <5 μ fractions of muscovite and biotite. Moreover, their data show that muscovite and biotite had comparable external surface area for the size range studied. This further strengthens the contention that the increase in the adsorption of hydroxy-aluminium polymers with the decrease of particle size is essentially because of the increase of external surfaces of micas (Table 1).

The data obtained in this study demonstrate the importance of the adsorption of hydroxy-aluminium polymers on the external surfaces of micaceous minerals. They also indicate that the differentiation of the hydroxy-aluminium polymers adsorbed on external surfaces of 2 : 1 expansible phyllosilicates from interlayer hydroxy-aluminium, particularly in the <0·2 μm fractions, deserves close attention in studies on, for example, ion fixation and selectivity, acidity and swelling of clays.

Nonisothermal Chemical Kinetics

IN a recent article[1], MacCallum and Tanner suggest that the traditional homogeneous reaction rate expression

$$\frac{dC}{dt} = A \exp(-E/RT)\, f(C) \qquad (1)$$

is applicable only to isothermal processes, and that an additional term

$$\left(\frac{\partial C}{\partial T}\right)_t \frac{dT}{dt} \qquad (2)$$

should be added when the temperature varies over the course of the reaction. This suggestion has several disturbing features. It implies, contrary to logic, that the instantaneous reaction rate depends not only on the present state of the system (the frequency of collisions and relative energies and orientations of all of the system molecules) but also—through dT/dt—on previous and future states. The proposed correction is impossible to calculate, because in a real system temperature cannot be varied holding time constant, and therefore the factor $(\partial C/\partial T)_t$ is devoid of physical meaning; moreover, even for the hypothetical case of a step-function change in temperature, the instantaneous change in concentration must be 0, which eliminates the correction. A particularly far-reaching implication of the suggestion is that essentially all of the nonisothermal reactor modelling and analysis that has taken place over the past 80 years has been fundamentally unsound, by virtue of having been based on equation (1).

We hold that the suggestion of MacCallum and Tanner is incorrect: equation (1) certainly has shortcomings, but they do not include the one proposed. Mathematically, the authors err in proceeding from the statement $C = f(t,T)$ to the equation

$$dC = \left(\frac{\partial C}{\partial t}\right)_T dt + \left(\frac{\partial C}{\partial T}\right)_t dT \qquad (3)$$

Equation (3) is valid if and only if C is a state function of the variables t and T. That it is not can be seen by considering two paths from an initial state (t_1, T_1) and concentration C_1 to a final state (t_2, T_2) (Fig. 1): the first path proceeds along an isotherm at T_1 to $t = t_2$, and then jumps instantaneously to $T_2 = T_1$, and the second path jumps immediately from T_1 to T_2 and then proceeds isothermally to $t = t_2$. The concentration C_2 in the first case lies on an isotherm at T_1, and in the second on an isotherm at T_2. Because these isotherms intersect at t_1, they cannot also intersect at t_2. The value of C_2 thus depends on the path taken from state 1 to state 2, and C is accordingly a path function rather than a state function. This violates the condition for the validity of equation (3), and negates the conclusions reached by MacCallum and Tanner, which are based solely on this equation.

We may then ask why the kinetic parameters of equation (1) are likely to be in error when evaluated using nonisothermal techniques, such as differential thermal

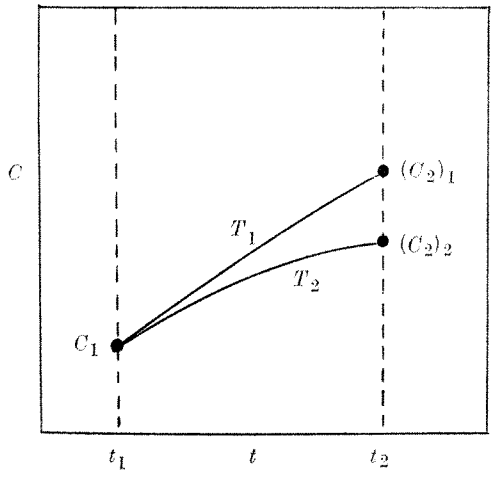

Fig. 1. Concentration as a function of time for two paths between (t_1, T_1) and (t_2, T_2).

analysis (DTA), or the thermogravimetric (TG) techniques referred to by MacCallum and Tanner. There are several possible explanations, apart from the inherent difficulty of obtaining precise measurements for nonisothermal systems. Everything that has been said about the temperature dependence of reaction rates is based on an implicit assumption of instantaneous thermal equilibrium, or something approximating it; if this assumption is invalid, then the concept of temperature loses its meaning. This equilibrium condition is certainly less likely to hold in nonisothermal than in isothermal systems, and consequently, as departures from isothermality increase, rate equations of the type of equation (1) become increasingly suspect. In extreme cases, it becomes necessary to invoke the formalism of nonequilibrium statistical mechanics to arrive at a meaningful description of the occurring rate processes.

On a less fundamental level, there is nothing at all sacred about the form of equation (1). The Arrhenius expression is a frequently erroneous semiempirical formula, with the temperature independence of the activation energy E and the pre-exponential factor A becoming increasingly questionable as the reaction temperature range broadens. Moreover, a fixed expression for $f(C)$ implies an invariant mechanism; even for isothermal conditions, the mechanism is sometimes a function of the extent of reaction, and it is common to find a varying mechanism (and therefore a varying $f(C)$) as the temperature changes.

Any of these circumstances might lead to errors of the type noted by MacCallum and Tanner, and their suggestion that isothermal methods be used whenever possible is reasonable. If the Arrhenius function is valid and the mechanism is fixed, however, equation (1) as written is applicable to nonisothermal systems, and if the driving function $T(t)$ in a DTA or TG experiment is accurately determined, then the conversion history is explicitly given by

$$C(t) - C(0) = \int_0^t \left(\frac{dC}{dt}\right) dt = \int_0^t A \exp\left[-E/RT(t)\right] f[C(t)]\, dt \quad (4)$$

BIOLOGICAL SCIENCES

IgG Synthesis in Hybrid Cells from an Antibody-producing Mouse Myeloma and an L Cell Substrain

Proliferating hybrid cell strains have been produced using Sendai virus to mediate fusion of a cloned, culture-adapted mouse plasmacytoma, MOPC 315 (my unpublished work with M. Potter), with the thymidine kinase deficient cell strain LM(TK$^-$) C1 1D (ref. 1), referred to as C1 1D. Because the hybrid cell strains contained soluble enzymes with the electrophoretic mobility characteristic of the inbred strains of mice from which MOPC 315 and C1 1D were derived, at least part of both parental genomes was expressed (my unpublished work with H. G. Coon). Here I report an investigation of the synthesis of immunoglobulin by clones of these hybrid cell strains.

In cell culture, MOPC 315 secretes easily detectable amounts of immunoglobulin with an A type heavy chain and lambda type light chain. This immunoglobulin has antibody activity against dinitrophenyl (DNP) groups[2] as does immunoglobulin found in the serum of mice with the MOPC 315 tumour. When tissue culture supernatant from five independently produced hybrid cell strains was concentrated and assayed by agar gel diffusion (Ouchterlony) for immunoglobulin, no reactions were observed. But what seems to have been a small amount of immunoglobulin with anti-DNP activity was detected by three more sensitive techniques.

The MOPC 315 immunoglobulin binds specifically to DNP attached to 'Sepharose'; the protein can then be eluted by a hapten, DNP-glycine[3]. Two different hybrid cell strains resulting from the fusion of MOPC 315 and C1 1D (referred to as D1 and D2), C1 1D, or MOPC 315 were incubated for 16 h in Eagle's medium with 1 per cent foetal calf serum, without lysine and threonine, to which 2 or 10 μCi/ml. of ^{14}C-lysine and ^{14}C-threonine (Schwarz Bioresearch) had been added. The supernatants were aspirated, dialysed exhaustively against a phosphate buffered saline (PBS), *p*H 7·4, and passed through DNP-'Sepharose' columns (1 × 5 cm). Each column was prepared from fresh DNP-'Sepharose' and used once only. After the radioactive culture supernatant had been applied, the columns were washed extensively with PBS, and then eluted with 1–2 ml. of a 20 mg/ml. solution of DNP-glycine (Sigma). The total radioactivity in trichloroacetic acid (TCA) precipitable protein was determined by the paper disk method[4]. The results are shown in Table 1. No radioactive protein was eluted by DNP-glycine from the DNP-'Sepharose' columns which received supernatant from C1 1D cultures. Some labelled protein was always eluted from columns receiving supernatant from the hybrid cell cultures.

Table 1. Elution by DNP-glycine (20 mg/ml.) of TCA precipitable labelled protein from DNP-'Sepharose'

	Cell strain	Total radioactivity (c.p.m.) eluted as TCA precipitable protein
Experiment 1	C1 1D	0
	Hybrid D1	130,012
	Hybrid D2	60,314
Experiment 2	C1 1D	0
	Hybrid D1	1,754
	MOPC 315	28,382

A different preparation of DNP-'Sepharose' and a different amount of ^{14}C-lysine and ^{14}C-threonine were used in each experiment. Supernate was obtained from incubations of approximately 5×10^6 cells of each strain in both experiments.

Radioimmunoelectrophoresis[5] was also performed on dialysed supernatant from cell cultures incubated with either amino-acids labelled with ^{14}C or with reconstituted protein hydrolysate similarly labelled (Schwarz Bioresearch). The hybrid cells secreted protein labelling the

precipitation arcs that identify A heavy chains, λ light chains, and anti-DNP activity. If F1 (C3H × Balb/c) mice were inoculated with C1 1D, MOPC 315 or the hybrid cells, tumours developed. The hybrid tumours appeared much later than either of the parent tumours, and the one tumour tested was not transplantable (Table 2). One of the C1 1D tumours and a hybrid D1 tumour were minced and incubated with labelled amino-acids as before. The hybrid tumour secreted material which labelled the A, λ, and anti-DNP activity precipitation arcs: supernatant from the C1 1D tumour labelled no precipitation arcs. Occasionally, supernatant from cultures of C1 1D labelled the A, λ, M, κ and anti-DNP activity precipitation arcs, when large numbers of C1 1D cells (usually $0{\cdot}5$–$1{\cdot}0 \times 10^8$) were incubated and either serum or urine from mice bearing the appropriate plasma cell tumour was used as a carrier. In two experiments when MOPC 315 protein purified from a column of DNP-'Sepharose' was used as a carrier, no labelling by C1 1D supernate was observed.

The Farr technique has been used to measure the equilibrium constant for MOPC 315 binding to DNP-L-lysine[6]. I examined concentrated supernatants from C1 1D, MOPC 315, hybrids D1 and D2 as well as hybrids produced from another plasma cell tumour in culture, MOPC 265, and C1 1D or the L cell strain, A9 (ref. 7). The MOPC 265 cell strain was adapted to cell culture by the technique of alternate cell culture and animal passage[8]. MOPC 265 secretes only a κ chain which does not bind DNP. The unbound DNP-L-lysine hapten is not precipitated by 50 per cent $(NH_4)_2SO_4$. Anti-DNP antibodies present in the culture supernatants bind DNP-L-lysine labelled with ^{14}C (given to me by R. Asofsky). Precipitation with 40 per cent $(NH_4)_2SO_4$ will then remove bound radioactive hapten from the supernatant (Table 3). Supernatants from the MOPC 315 × C1 1D hybrid cultures removed 20–30 per cent of the radioactivity. Supernates from the MOPC 265 × C1 1D MOPC 265 × A9 and from C1 1D cell strains did not contain proteins which bound DNP-L-lysine.

Table 2. TUMOUR PRODUCTION IN F1 (C3H × Balb/c) MICE

Cell strain	Injected	Takes		Transplantable
C1 1D	4	4	Appeared within 44 days	Yes
MOPC 315	6	6	Appeared within 30 days	Yes
Hybrid D1	6	5	Appeared after 60 days	No
Hybrid D2	3	2	Appeared after 90 days	Not tested

Cells (usually 5×10^6–1×10^7) were inoculated subcutaneously into each host. The hybrid D1 was not transplantable; both C1 1D and MOPC 315 were. The C1 and 1D strains were derived from a C3H mouse; MOPC 315 from a Balb/C2 mouse.

Table 3. AMMONIUM SULPHATE PRECIPITATION OF PROTEINS BINDING ^{14}C LABELLED DNP-L-LYSINE

	Source of supernatants	Radioactivity (c.p.m.) left in supernatant fluid (50 μl.)	Per cent removed
Experiment 1	Culture media only	332	0
	C1 1D	322	3
	Hybrid D1	236	29
Experiment 2	Culture media only	186	0
	C1 1D	183	2
	Hybrid 265 × C1 1D	191	0
	Hybrid 265 × A9	184	1
	Hybrid D1	149	20
	Hybrid D1	144	23
	Hybrid D2	130	30

Supernatants were aspirated from cultures between 45 and 90 days after cell fusion and were concentrated twenty times by vacuum dialysis. Supernatants (0·1 ml.) and radioactive hapten (0·1 ml.) were incubated for 1 h at 37° C before precipitation in 50 per cent $(NH_4)_2SO_4$.

These data suggest that these MOPC 315 × C1 1D hybrid cells secrete a small amount of DNP-binding protein which may be identical to the immunoglobulin secreted by the MOPC 315 cell strain. Less immunoglobulin is synthesized than in MOPC 315. The hybrid cells may lack the intracellular organization (membrane systems) needed to secrete large amounts of protein. It may also be that the mixing of two different cell strains with variant translation mechanisms[9,10] results in a hybrid cell strain that secretes an altered immunoglobulin undetectable by the analytical methods used.

I thank Dr Michael Potter and Professor Hayden Coon for help and encouragement.

Induction *in vitro* of Hapten Specific Plaque Forming Cells

THE method developed by Mishell and Dutton[1] for the *in vitro* stimulation of an apparently primary response to red cell antigens offers advantages over *in vivo* experiments in analysing the cellular basis of the immune response. The possible uses of the *in vitro* system would be much increased were it possible to get reproducible responses to a well defined hapten.

Success in achieving this with the dinitrophenyl group as hapten has been reported by Segal *et al.*[2] using explants of mouse spleen and lymph nodes, and also by Kettman and Dutton[3] using single cell suspensions and the trinitrophenyl group as hapten. We have shown that cells producing antibodies to the hydroxy-nitro-iodophenyl group (NIP) can be induced in mouse spleen cell suspensions. The response is erratic unless the donors of the spleen cells have been primed by injection of the red cell to which the hapten is attached to form the *in vitro* inducing antigen.

Both Balb/c and F1 hybrid C57Bl/6 × DBA/2 mice were used. The haptens and related chemicals used[4] were 4-hydroxy-3-iodo-5-nitrophenacetyl azide (NIP-Az), 4-hydroxy-3-nitrophenacetyl azide (NP-Az), 4-hydroxy-3-nitrophenacetylamino-N-caproic acid (NP-CAP) and 4-hydroxy-3-iodo-5-nitrophenacetylamino-N-caproic (NIP-CAP). The culture media and conditions of culture of spleen cell suspensions, the collection of the cells and the haemolytic plaque assay, were all similar to those described by Mishell and Dutton[1]. Exact adherence to the culture conditions and the use of media screened for effectiveness was necessary to obtain satisfactory results. The method of coupling haptens to red cells was modified from that of Pasanen and Mäkelä[5]. To prepare inducing antigens a 10 per cent red blood cell suspension was coupled with $2{\cdot}5 \times 10^{-3}$ M NIP-Az in 0·125 M carbonate–bicarbonate buffer, *p*H 9·25 at 4°, for 30 min. Both NIP-coupled sheep red cells (NIP-SRBC) and NIP-coupled rabbit red cells (NIP-RRBC) were used. No cross reactivity between sheep and rabbit red cells was observed. To assay cells forming antibody to the NIP determinant, NIP-coupled donkey red cells (NIP-DRBC) were used ($7{\cdot}5 \times 10^{-4}$ M NIP-Az in 0·125 M carbonate–bicarbonate buffer, *p*H 9·25 at 4°, for 30 min). Using this ratio of reagents gives a

maximum of plaques and the reacted cells are stable and can be used for several days after coupling. NIP-coupled donkey red cells were chosen to assay the cells which form NIP antibody because they gave no detectable reaction with anti sheep red cell antibody and yielded very few background plaques in the control cultures using SRBC as antigen. The specificity of the assay for cells synthesizing antibodies to the NIP hapten was demonstrated by the 90 per cent inhibition of plaque-formation by NIP-CAP at 5×10^{-5} M. At the same concentration NP-CAP had little or no inhibitory power. Moreover, neither NIP-CAP nor NP-CAP at this concentration inhibits plaques on SRBC.

Table 1. RESPONSE OF SPLEEN CELL CULTURES FROM CARRIER RED CELL IMMUNIZED AND UNIMMUNIZED MICE TO INDUCTION WITH NIP-COUPLED RED CELLS

Experiment	Cells from mice immunized with carrier RBC Antigen added		Cells from unimmunized mice Antigen added	
	NIP-SRBC	SRBC	NIP-SRBC	SRBC
1	1,531	33	342	43
2	1,492	66	17	25
3	2,185	68	433	22
4	1,022	40	—	—
5	857	12	86	12

	10^{-4} M NP-CAP	778	76	2,320	154
	10^{-4} M NIP-CAP	333	32	1,810	120

Inhibitors added at same time as the inducing antigen, NIP-SRBC. Number of plaque formers is given per 10^6 recovered cells, Day 5.

When spleen cells from unimmunized mice were cultured with NIP-coupled sheep or rabbit red cells and the culture tested after 3, 4, 5 and 6 days by the plaque assay using NIP coupled donkey red cells, the maximum number of plaque forming cells were found after 5 days. The same kinetics of response were found when cells that form plaques on SRBC were assayed in cultures that had either coupled or uncoupled sheep cells as antigen. In the hapten system, using spleen suspensions from unimmunized mice, about half the cultures contained a significant number of cells synthesizing antibodies to the hapten (Table 1). The number of plaque forming cells induced with hapten was between one and twenty times greater than the number in control cultures, to which either unsubstituted red cells or no red cells had been added. We thought that a better hapten response was obtained with older mice and this, together with other reports of spontaneous immunization of mice against sheep red cell antigens[6], suggested that the origin of the very variable hapten response might lie in differences in the state of immunity to sheep or rabbit red cells of the donor mice.

To attempt to augment the hapten response we then used, in culture, spleens of mice primed by a single intraperitoneal injection of 0·5 ml. of 1·25 per cent suspension of either sheep or rabbit red cells. When the spleen cells of these immunized animals were cultured with NIP coupled to the kind of red cell used for immunization a consistently high response of anti-hapten plaque forming

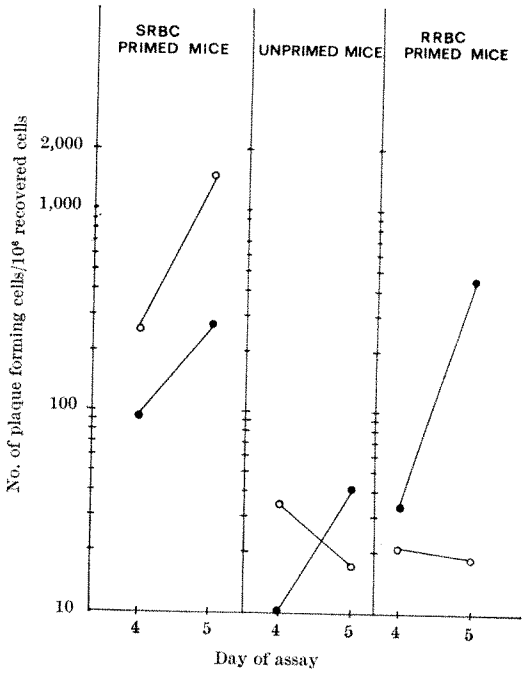

Fig. 1. Specificity of effect of immunization by carrier cell; plaque formers are assayed on NIP-DRBC. Immunized Balb/c mice used as donors of spleen cells were primed by injection of SRBC or RRBC, 33 days before setting up cultures. Antigens used in culture: ○, NIP-SRBC; ●, NIP–RRBC.

cells was obtained (Table 1). The enhanced response was specific for the cell used for immunization, being an order of magnitude higher when the hapten was coupled to the immunizing red cell compared with the response when the hapten was coupled to a non-cross reacting red cell or if unimmunized animals were used in the same experiment (Fig. 1). The effect on hapten response of prior immunization with the carrier red cell is only seen when the *in vitro* inducing antigen is the hapten coupled to the red cell used for immunization of the donor animal. Moreover, a poor response occurred when NIP-RRBC and SRBC were added to a culture of spleen cells from a mouse which had been immunized against SRBC. The effect of prior immunization was particularly large when 3–4 month old Balb/c mice were used (Fig. 1). It was smaller with 6–7 month old hybrid mice (Fig. 2). The cells from unimmunized mice sometimes gave a good response (Table 1), as we have already pointed out.

In a preliminary investigation enhancement of the antihapten response was estimated at varying times after injection of red cells. No effect was apparent after 4 days and little after 13 days, but a consistently positive response was obtained from spleens 30–60 days after injection. In contrast there was a strong anti-SRBC response in cultures of cells taken from animals immunized 4 days previously.

The hapten specificity of the induction with NIP-coupled SRBC using spleen cells from immunized mice was tested by addition of NIP-CAP or the non-cross reacting hapten NP-CAP to the cultures together with the NIP-coupled red cells. At a concentration of 10^{-4} M of NIP-CAP there was about 75 per cent inhibition of formation of cells giving plaques on NIP-DRBC but no inhibition of cells giving plaques on SRBC (Table 2). At the same concentration the inhibition by NP-CAP was much lower and is probably not significant.

We tried to evaluate the contribution of the spleen cells from mice immunized with red cells to the anti-hapten response. We mixed various proportions of cells from spleens of primed and unprimed mice and tested their capacity in culture to produce plaque forming cells on NIP-DRBC. At a ratio of 1/4 of primed/unprimed cells

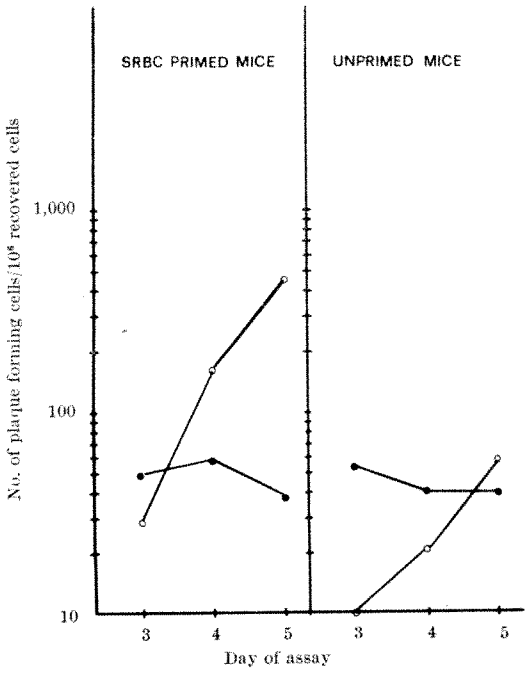

Fig. 2. Effect of prior immunization by carrier red cell; plaque formers are assayed on NIP-DRBC. Immunized F1 hybrid C57Bl/6×DBA2 mice were primed by an injection of SRBC 44 days before setting up cultures. Antigens used in culture: ○, NIP-SRBC; ●, none.

there was no diminution in the plaque forming cells, which suggested that at least two cells were involved in the anti-hapten response, and that the carrier specific cell in the spleen from a primed animal was in excess over the hapten specific cell.

Cells synthesizing antibodies to a hapten can be induced consistently *in vitro* by hapten coupled to red cells and by using spleen cells from mice immunized previously with the red cell carrier. When spleen cells from unimmunized mice are used, the response is variable. Because prior immunization with the carrier erythrocyte seems to be essential for hapten response some correlation between the *in vitro* response to the hapten and to the carrier cell might be expected. This was found insofar as the highest responders to one specificity were the highest to the other and the lowest also the lowest, but intermediate values did not correspond. This may be related to the fact that dilution of the primed cells with cells from unimmunized animals showed that the primed cells were in excess. The specificity of induction by the hapten seems clear, as does the specificity of the carrier cell.

The results with the hapten carrier complex could be interpreted in terms of current hypotheses[7] as being a consequence of cooperation of cells primed against the carrier with cells capable of synthesizing antibodies to the hapten.

We thank Mrs Joan Rankin for technical assistance, and Drs N. A. Mitchison, P. Plotz, G. Fleet and A. Munro for haptens. E. S. L. received partial research support from the US Public Health Service.

Mechanism for Joining *V* and *C* Genes

I would like to suggest an alternative to the mechanism suggested by Gally and Edelman[1] for the joining of the *V* gene to the *C* gene. This mechanism has three principal features: (1) no "cross-over" event (for excision and integration) is required; (2) the joined product, the coupled *VC* into one gene, could either be an RNA or a DNA molecule; and (3) the *C* gene in its joining end must have a few redundant bases which are almost identical to the joining end of the *V* gene.

Consider the genes *V* and *C* in Fig. 7 of Gally and Edelman's article and assume that the attachment site is the overlap region in the joining ends of *V* and *C* genes (Fig. 1*a*). Let the transcription enzyme transcribe opposite strands of *V* and *C* genes to generate a partially double stranded RNA molecule. Alternatively, these could be as in Fig. 1*b*, single stranded pieces of DNA. At this point a repair enzyme together with a ligase converts it into a double stranded molecule which would now replicate with the help of a replicase (Fig. 1*c*). A mechanism to generate diversity could be introduced by errors in the repair process; in this case the heterozygous molecule must segregate very early.

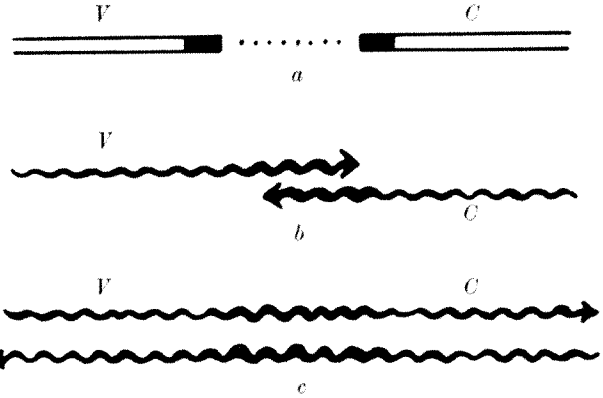

Fig. 1. The joining of *V* and *C* genes. See text for explanation.

This self replicating, intermediate template might be a special inheritable material of somatic cells producing immunoglobulin in very large amounts. If such templates are present they would perhaps be unique to immunoglobulin producing cells or cells similar to it—which require to produce many adventitious specificities built into molecules which also share common specificities.

Another mechanism of joining *V* and *C* genes is suggested in Fig. 5 of ref. 1; excision of the genetic region between the right end of any *V* gene and the left end of the *C* gene will achieve the joining by only one "cross-over" event.

Cyclophosphamide Tolerance as a Test for Antigenicity of Nucleic Acids

It has been generally thought that nucleic acids are unable to elicit an immune response without carrier protein and adjuvant[1]. We have recently succeeded in accelerating the spontaneous formation of antibodies to RNA and DNA in New Zealand mice with polyinosinic · polycytidylic acid (poly I·C) without carrier protein or additional adjuvant[2]. We have also made New Zealand mice immunologically tolerant to subsequent challenge with poly I·C in complete Freund's adjuvant by pretreatment with poly I·C followed by cyclophosphamide[3]. These studies in mice that spontaneously develop antibodies to nucleic acids suggested that poly I·C was immunogenic but did not prove that nucleic acids could be recognized immunologically by normal mice. We now report the induction of immunological tolerance to poly I·C in normal strains of mice as a method of demonstrating immunological recognition of this nucleic acid.

Multiple injections of poly I·C without adjuvant failed to immunize three normal strains of mice[3]. We have further attempted to detect very low levels of antibody to poly I·C in C57Bl/6, Balb/c, and C3H/He mice treated with twelve injections of poly I·C (75–100 μg/injection). Antigen binding capacities by the ammonium sulphate precipitation method[3] have been less than 0·04 μg/ml., the limit of sensitivity of our assay.

To study further whether normal strains of mice immunologically recognize poly I·C without carrier or adjuvant, we tried to induce immunological tolerance with cyclophosphamide. One month old Balb/c and DBA/2, and 1–3 month old C57Bl/6 mice of both sexes were injected intraperitoneally with either poly I·C (100 μg) or bovine γ-globulin, BGG (500 μg, not ultracentrifuged), and 24 h later given cyclophosphamide intraperitoneally (75 μg/g body weight). Eight days later all mice were challenged intraperitoneally with 150 μg of poly I·C in complete Freund's adjuvant. Antibody levels measured 13 days later by the ammonium sulphate precipitation assay[3] are listed in Table 1. Much lower levels of antibody to poly I·C were found in mice pretreated with poly I·C plus cyclophosphamide than in control mice pretreated with BGG plus cyclophosphamide. Thus these mice were made immunologically hyporesponsive to challenge with poly I·C in adjuvant by pretreatment with poly I·C plus cyclophosphamide, indicating that immune cells were induced to proliferate by antigenic recognition of poly I·C and were destroyed by the cyclophosphamide.

Table 1. TOLERANCE TO POLY I·C IN NORMAL MICE

Strain*	Mean poly I·C binding capacity (μg/ml.) BGG plus cyclophosphamide	Poly I·C plus cyclophosphamide†
C57Bl/6	1·5	< 0·04
Balb/c	6·1	0·2
DBA/2	8·7	0·6

* Twenty animals in each group.

† $P < 0.01$ compared with BGG controls for each strain (t test).

The specificity of the tolerance to poly I·C was investigated in DBA/2 and C57Bl/6 mice. These mice were treated with poly I·C plus cyclophosphamide and then immunized with sheep erythrocytes. Antibody forming cells to sheep erythrocytes were enumerated by the Jerne plaque assay. Mice made tolerant to poly I·C made normal immune responses to sheep erythrocytes, indicating that the tolerance to poly I·C showed immunologic specificity.

Using this technique of cyclophosphamide induced tolerance, we have also found that a double stranded DNA, dAT, is antigenic in New Zealand mice.

The exact mechanism of this phenomenon is not clear. We may be eliminating the small number of cells capable of responding to the nucleic acid, a number perhaps too small to produce a detectable antibody response witho adjuvant. On the other hand, if cooperation of two c types is necessary for the response to the antigen adjuvant, we may be selectively eliminating one of t populations of cells necessary for the response. Whatev the exact mechanism, cyclophosphamide tolerance m be a useful test for the antigenicity of a variety of su stances which, like nucleic acids, have not previous been thought to be recognized immunologically.

Antigenic Determinants in Amyloid Deposits

Precise analyses of human amyloid laden tissues ha shown that they contain at least two specific components- a fibrillar protein of uniform cross-sectional diameter and a rod-shaped protein (P-component). Units of t latter look pentagonal under the electron microscope a show antigenic identity with an α-globulin present human plasma[3–5]. Preliminary studies have also suggest that the fibrillar component of amyloid is non-immun genic whereas the P-component is capable of eliciting strong antibody response[6–8]. Recently, we have succeed in preparing antisera not only to the P-component b also to alkali degraded amyloid fibrils (DAM), according the method of Pras *et al.*[9]. Here we show that the antisera react not only with DAM but also with amylo

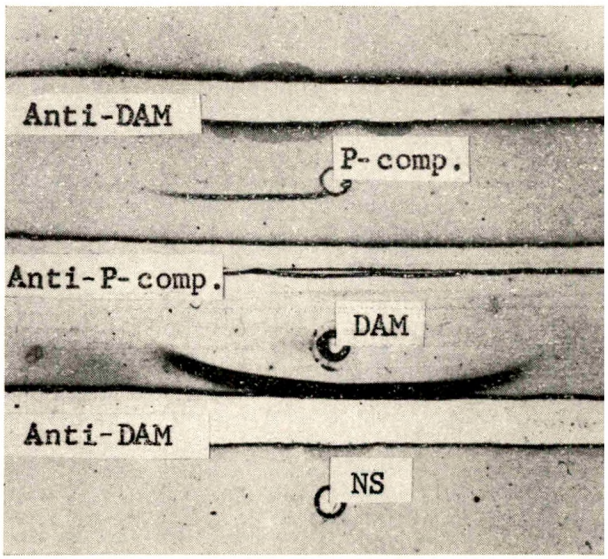

Fig. 1. Immunoelectrophoresis of amyloid components. P-component (P-comp.) forms a single precipitin line against anti-P-component antiserum (anti-P-comp.) but fails to react with anti-DAM antiserum: DAM forms a single precipitin line against anti-DAM antiserum but fails to react with anti-P-comp. Normal serum (NS) fails to react with anti-DAM.

deposits in various tissues, particularly liver, spleen and kidney. Data are also presented which compare the tissue reactivity of anti-DAM and anti-P-component antisera measured by the fluorescent antibody technique.

No identity between P-component and DAM was detectable by the Ouchterlony technique. By immunoelectrophoresis, P-component did not react with antiserum to DAM and DAM did not react with antiserum to P-component (Fig. 1). As has been seen before, normal serum formed a single precipitin line when tested against antiserum to P-component; antiserum to DAM, on the other hand, failed to react with normal serum (Fig. 1). The fluorescent antibody studies were performed on 8 μm thick sections of liver, spleen and kidney, snap frozen in a mixture of dry ice and acetone immediately after the deaths of two patients with primary amyloidosis, AM-Sn and AM-Gi, and two patients without amyloidosis, NL1 and NL2. Appropriate blocking controls included pretreatment of non-amyloid and amyloid laden tissues with non-immune rabbit serum and rabbit antiserum to human immunoglobulin G (IgG). For these studies all antisera were adsorbed several times with a lyophilized powder containing non-amyloid liver, kidney and spleen. Antisera to P-component and to DAM were further adsorbed with human neonatal cord blood which was previously shown to contain neither P-component[10] nor DAM. The indirect or "sandwich" technique was adopted using fluorescein labelled anti-rabbit globulin antiserum.

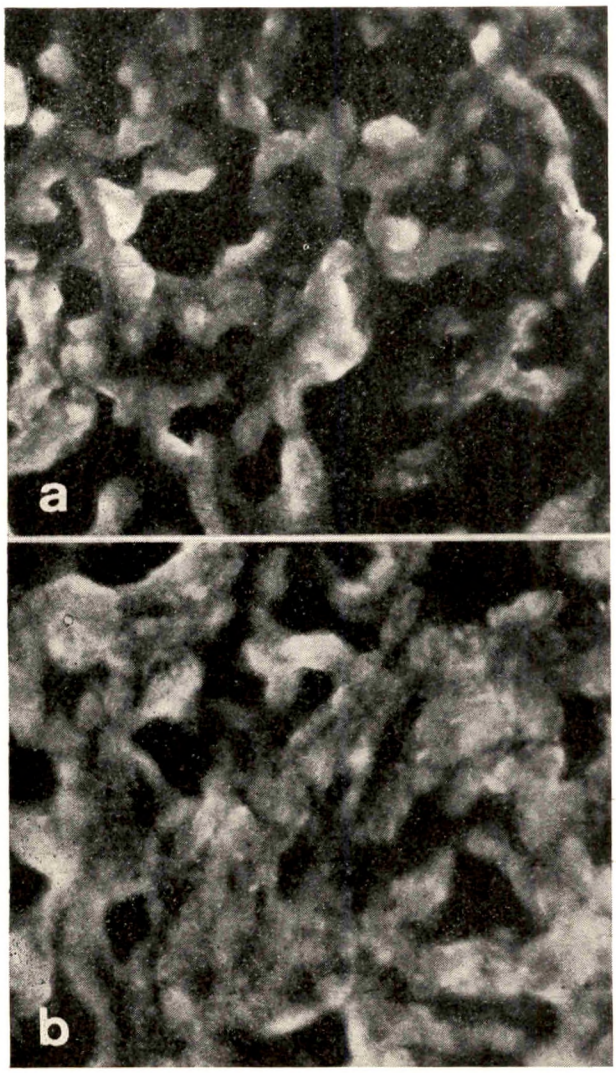

Fig. 2. (*a*) Amyloid deposits in liver AM-Sn reacted with fluorescein-labelled anti-DAM antiserum. (*b*) Amyloid deposits in liver AM-Sn reacted with fluorescein-labelled anti-P-component antiserum.

Areas of bright fluorescence corresponding to deposits of amyloid as observed by polarization microscopy after Congo red stain were discernible in sections of liver (Fig. 2), kidney and spleen from both patients with amyloidosis. No specific differences in the patterns or localization of fluorescence achieved by either anti-P-component or anti-DAM antisera could be ascertained although the anti-P-component antiserum invariably provided brighter and more intense fluorescence of the amyloid deposits than the anti-DAM antiserum. Anti-human IgG antiserum produced weak fluorescence in the tissues of one of the amyloid subjects, AM-Sn (Fig. 2), and in the glomeruli of one of the non-amyloid controls (NL1). Non-specific fluorescent staining was minimal and no fluorescence was visible in the non-amyloid tissues after the addition of anti-P-component or anti-DAM antisera, respectively. We also saw relatively less bright but definite autofluorescence in the amyloid deposits before the addition of specific antisera.

Previous studies using fluorescent antibody techniques suggested that amyloid deposits were composed of immune complexes by virtue of their reactivity with IgG and the C3 component of complement[11,12]; but it was later shown by more precise immunochemical techniques that neither of these proteins is specific for amyloid[13]. This study reveals that amyloid deposits, which by light microscopy appear to be homogeneous, have at least two distinct and specific antigenic determinants, one related to the amyloid fibril and one related to the P-component. Moreover, the availability of monospecific antisera to each of these two antigenic determinants should make it possible to differentiate between the parts these two as yet unrelated proteins play in the pathogenesis of human amyloidosis. It is also hoped that more extensive studies using labelled antisera to amyloid components will provide a new diagnostic method for detecting the presence of amyloid in various biopsy specimens.

These investigations were supported by the US Public Health Service, the Massachusetts Chapter of the Arthritis Foundation, and the Arthritis Foundation. We thank Linda Burnett and David Feigenbaum for technical and photographic assistance.

Effect of Skeletal Muscle Native Tropomyosin on the Interaction of Amoeba Actin with Heavy Meromyosin

ACTIN and myosin, recently identified in protozoa and myxomycetes, are presumably responsible for the motility of these organisms[1–5]. Control of this motility is, however, not at all understood. In skeletal muscle, contraction is partly under the control of the protein complex, native tropomyosin which is believed to bind to the actin filaments[6,7]. In the presence of Ca^{2+}, native tropomyosin allows the interaction of actin and myosin filaments to occur whereas in the absence of Ca^{2+} native tropomyosin inhibits this interaction[6], probably by inhibiting the binding of actin to myosin[8]. No protein like native tropomyosin has yet been identified in a primitive contractile system, but we know that *Acanthamoeba* actin activates the ATPase of skeletal muscle heavy meromyosin (HMM) and we have used this fact to investigate the effect of skeletal muscle native tropomyosin on the interaction of *Acanthamoeba* actin with HMM. We have found that native tropomyosin in the presence of Ca^{2+} increases the activation of HMM ATPase by *Acanthamoeba* actin, while in the absence of Ca^{2+} the native tropomyosin inhibits this activation.

Amoeba actin was isolated by the method of Weihing and Korn[4]. After elution of the actin from 'Sephadex', it was concentrated by dialysis against dry 'Sephadex G-200', and then polymerized by dialysis against two changes of 0·1 M KCl–0·5 mM ATP–0·5 mM 2-mercaptoethanol–2·0 mM imidazole (*p*H 7·0). Skeletal muscle actin was isolated by the method of Adelstein *et al.*[9], and F-actin was prepared and taken into solution as described previously[11]. Skeletal muscle myosin and heavy meromyosin were prepared by the method of Kielley and Harrington[15] and Eisenberg and Moos[11] respectively. Native tropomyosin was prepared by the method of Hartshorne and Mueller[12] except that 5 mM 2-mercaptoethanol rather than 2 mM dithiothreitol was used. ATPase activity was assayed using the *p*H-stat as previously described[10]. ATP was purchased from Sigma and ethylene glycol-*bis*-(β-aminoethyl ether)-N,N′-tetraacetic acid (EGTA) was a gift from the Geigy Chemical Co.

Acanthamoeba actin activated the HMM ATPase although it was only about one quarter as effective as skeletal muscle actin under identical conditions (Table 1). Furthermore, as for skeletal muscle actin, in the absence of native tropomyosin, EGTA and Ca^{2+} had no effect on the amoeba actin activation of the HMM ATPase. Conversely, in the presence of Ca^{2+}, native tropomyosin caused a marked increase in the amoeba actin activation of the HMM ATPase. In identical conditions, a similar increase in skeletal muscle actin activation of the HMM ATPase was not observed, but in conditions where the Mg^{2+} concentration was less than or equal to that of ATP, native tropomyosin did induce such an increase in both the actomyosin and the acto-HMM ATPases[8,13].

Table 1. EFFECT OF NATIVE TROPOMYOSIN ON AMOEBA AND RABBIT ACTIN ACTIVATION OF HEAVY MEROMYOSIN ATPase

Native tropomyosin	Activation (μmoles/mg min) EGTA		Ca^{2+}	
	Rabbit actin	Amoeba actin	Rabbit actin	Amoeba actin
−	0·67	0·15	0·64	0·15
+	0·04	0·036	0·54	0·44

All samples contained 2 mM ATP, 4 mM $MgCl_2$, 9 mM KCl, 0·2 mg/ml. of amoeba or rabbit actin, 0·28 or 0·56 mg/ml. HMM and either 1 mM EGTA or 0·1 mM $CaCl_2$. Samples with native tropomyosin contained 0·25 mg/ml. native tropomyosin. The ATPase activity of HMM in the absence of actin is shown in Fig. 1.

Of course, the key effect of native tropomyosin *in vivo* is presumably inhibition of the actin–myosin interaction in the absence of Ca^{2+} (ref. 6), and as can be seen from Table 1, in the presence of the Ca^{2+} chelator EGTA, native tropomyosin does indeed cause a marked decrease in both the amoeba actin and skeletal muscle actin activation of the skeletal muscle HMM ATPase. Because native tropomyosin binds to actin, but apparently does not bind to myosin[14], the present data suggest that skeletal muscle native tropomyosin binds to amoeba actin and affects its activity.

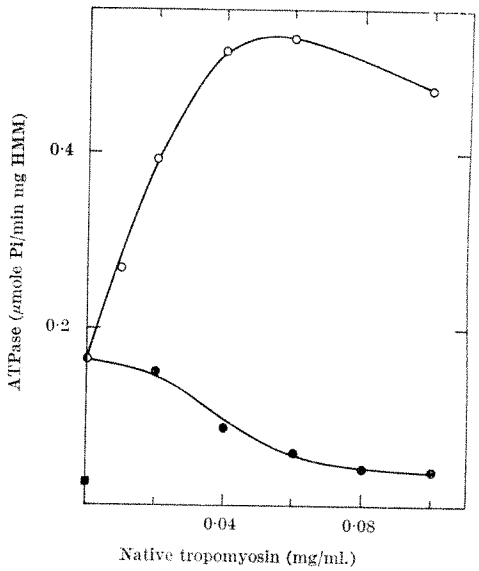

Fig. 1. Effect of native tropomyosin concentration on amoeba actin activation of heavy meromyosin ATPase. All samples contained 2 mM ATP, 4 mM $MgCl_2$, 11 mM KCl, 0·2 mg/ml. amoeba actin, 0·57 mg/ml. heavy meromyosin. ○, 0·1 mM $CaCl_2$; ●, 1 mM EGTA; ■, ATPase of heavy meromyosin in the absence of actin.

Further evidence for this suggestion is demonstrated in Fig. 1 which shows the effect of varying native tropomyosin concentration on the amoeba actin activation of HMM ATPase in the presence of either EGTA or excess Ca^{2+}. Both the activation in the presence of Ca^{2+} and the inhibition in the presence of EGTA level off when the ratio of native tropomyosin to amoeba actin is about 1 to 3 by weight which is similar to the 1 to 2 weight ratio observed with skeletal muscle actin (unpublished data of E. E. and W. W. Kielley). Furthermore, the native tropomyosin inhibition in the presence of EGTA reduces the acto-HMM ATPase almost to the level of that of the HMM alone. Thus skeletal muscle native tropomyosin has a clear effect on amoeba actin activation of skeletal muscle HMM ATPase. Furthermore, because this effect occurs at a relatively low ratio of native tropomyosin to actin it presumably occurs through the specific binding of native tropomyosin to amoeba actin rather than through some non-specific interaction. The clear implication therefore is that amoeba actin has sites for the binding of native tropomyosin. Whether such sites occur on amoeba actin because a protein similar to native tropomyosin occurs in *Acanthamoeba* or whether in fact all actins have such sites even if they do not play a part *in vivo* is not yet known. Attempts are in progress, however, to isolate native tropomyosin-like proteins from *Acanthamoeba*.

We thank Drs W. W. Kielley and E. D. Korn for helpful discussions, and Mr Louis Dobkin and Miss Paddy L. Wright for technical assistance.

Long Range Coherence and the Action of Enzymes

SOME time ago it was proposed that the energy produced in biological activities is partly stored in various materials through excitation of coherent electrical vibrations (polarization waves). If strong enough, such excitations can be stabilized through non-linear effects leading to various types of deformations[1,2]. R. Ferreira (personal communication) has suggested that such considerations might be of importance for an understanding of the action of enzymes. In fact the properties of a model which I have considered recently (unpublished) seems to support this idea.

The model consists of a system of interacting vibrating electric dipoles suspended in a neutral fluid with whose compressional modes they interact in a non-linear way. This system contains the case treated in appendix I of ref. 1. The electric polarization field P of the dipoles will be (but need not be) restricted to one direction. For weak excitation, this system behaves in the usual way, that is, it exhibits polarization waves whose frequency is very insensitive to the wavelength, and whose energy U is proportional to $\overline{P^2}$, the mean value of P^2. For larger excitations, however, the system shows remarkable properties, the most important being the establishment of a metastable state characterized by a non-vanishing mean value P_+ of P, that is, by a permanent mean displacement as it is found in ferroelectric materials. In the present case, however, this state is metastable; it has a higher energy than the undisplaced ground state though it is stable against small displacements. This metastable state is best reached through excitation of coherent modes which have very different characteristics from non-coherent ones. As a consequence of non-linear properties of the model, excitation of a certain amount of incoherent vibrations in the metastable state will lead as an immediate mechanical consequence to excitation of a coherent mode—quite apart from the further arguments for such excitation given in ref. 2.

Assume now that the model may be applicable to enzyme molecules which would possess metastable excited states in which polar groups are stretched so that the molecule may have a very large dipole moment resembling a ferroelectric case, and in which excitations above this state are partly transformed into coherent vibrational modes. An enzyme molecule so excited will have strong long range interaction with other molecules. This interaction will tend to lift other enzyme molecules into the metastable state, the required energy to be provided from the coherently excited modes. The interaction will also lead to attraction of other types of molecules (substrates) to the excited enzyme molecule, especially when they possess a proper frequency close to that of the coherent modes. It is therefore likely that the total energy of the complex of stretched enzyme and substrate is lower than it would be otherwise and this may facilitate the relevant chemical processes in the substrates.

Some of the properties of our model resemble Koshland's hypothesis of conformational changes[4] but they go much further because they imply a stretching of dipoles throughout the large enzyme molecule rather than a deformation near the active site. A principal consequence is the occurrence of the new long range forces which are likely to dominate the dynamic behaviour.

We thus arrive at the following dynamic picture. Assume the first substrate–enzyme complexes to be formed by fluctuations. The energy liberated by the relevant chemical transformations leaves the enzyme molecules coherently excited near their metastable state; return to the ground state would take a relatively long time. Through the long range forces so established they will (*a*) assist other enzyme molecules to transfer to the metastable state and (*b*) attract further substrates. The energy liberated by the chemical processes so acts as a pumping device. At this first stage the number of activated enzyme molecules—and therefore chemical processes—will consequently increase at an accelerating rate, much as in a chain reaction. This will continue until most enzyme molecules are in the metastable state after which the process will continue in a normal way.

These proposals could be tested in three ways. First, by investigation of the build-up of the reaction rate (first stage; chain-like process) as a function of the enzyme density. Second, by direct observation of the excited coherent modes. These modes are optically inactive. Use of Raman effect would, therefore, be appropriate. Through surface effects weak coherent radiation might, however, be observable. Third, by the detection of increase in the static dielectric constant as a result of the expected large increase in the dipole moment of the enzyme molecules when they are transferred to the metastable state.

G_{M1}-gangliosidosis Types 1 and 2: Enzymatic Differences in Cultured Fibroblasts

G_{M1}-GANGLIOSIDOSIS occurs in two clinical forms[1,2]. Type 1 resembles Hurler's syndrome somatically, but its psychomotor aspect is apparent from birth and progresses rapidly to cause death by 2 years of age. Type 2 presents no Hurler signs and its psychomotor course, though similar to that in type 1, is neither congenital nor is rapidly progressive; death occurs about 5 years of age. In addition to the accumulation of G_{M1}-ganglioside in neural, and to a lesser extent in extraneural, tissues both types share a profound, generalized deficiency of lysosomal β-galactosidase, with storage and excretion of modified keratin sulphates. Although the clinical and biochemical definition of the type 2 form is very recent[3], failure to observe both clinical types within single sibships is sufficient to suggest that each is caused by a different mutant gene. To test this hypothesis we have examined the gangliosides, glycosaminoglycans and residual β-galactosidase activities in fibroblast cell strains derived from skin in the deltoid area of patients with each type of G_{M1}-gangliosidosis. This communication deals only with the last focus of interest.

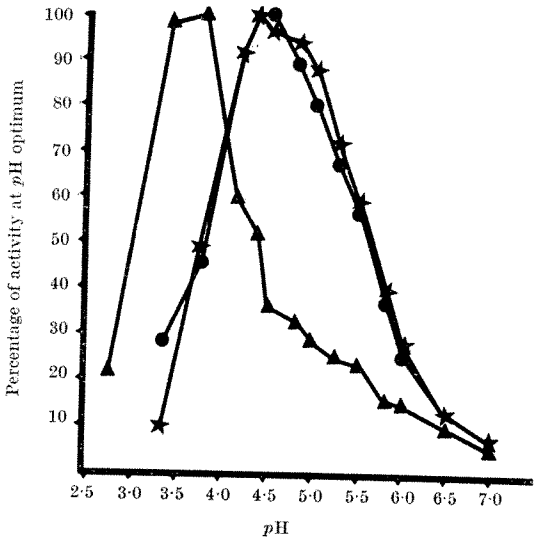

Fig. 1. The *p*H activity curve of β-galactosidase in fibroblasts of a control and both types of G_{M_1}-gangliosidosis. The buffer was 0·1 M citrate-phosphate. Results are expressed as a percentage of the activity at the optimum *p*H for each cell strain. ▲—▲, G_{M_1}-Type 1; ●—●, G_{M_1}-Type 2; ★—★, control.

The cell strains were developed according to Krooth[4] and maintained in Eagle's MEM supplemented with pyruvate, non-essential amino-acids[5], and calf serum (6 per cent foetal and 6 per cent newborn). Monolayers of comparable population density were harvested by successive, short incubations (5 min) in versene and trypsin[6]. The cells ($5–20 \times 10^6$) were then washed twice in 12 ml. of 0·9 per cent NaCl, resuspended in 1 ml. of 0·2 per cent Triton X-100, and sonically disrupted by four 30 s exposures to the 1 cm probe in an MSE sonicator set at 2 μm. After centrifugation of the sonic extract at 20,000*g* for 30 min, the supernatant was used as a source of lysosomal β-galactosidase. The enzyme assay used the fluorogenic substrate, 4-methylumbelliferyl-β-D-galactopyranoside, and was modified from Ockerman[7]. The assay was linear for 1 h at 37° C over the entire range of activities measured, if not less than 120 μg of cell protein was added to the reaction mixture as the source of enzyme. The sensitivity of the fluorometric procedure was essential for dealing with the much reduced β-galactosidase activities in both types of mutant cell strain.

The pronounced deficit of *p*H 5 β-galactosidase activity in both mutant cell strains is shown in Table 1. The greater deficiency in fibroblasts from patients with type 1 G_{M_1}-gangliosidosis is in accord with the relative clinical severity of this form of the disorder. It would be surprising if the major clinical differences between the two types of gangliosidosis were to be reflected only by a relatively slight quantitative difference in the residual β-galactosidase activity of their respective cultured fibroblasts. Indeed, important qualitative differences were soon discovered. Fig. 1 depicts the *p*H dependence of β-galactosidase activity in control and mutant fibroblasts. The activity in type 1 cells had a peak extending from 3·35–3·75, while the activity in type 2 cells closely resembled the control with a peak extending between 4·35–4·5. An equally decisive difference between the two types of mutant fibroblasts was reflected in the thermolability of their respective residual β-galactosidase activities (Fig. 2). Again, the type 2 cells were like the control, whereas the type 1 cells were quite different.

† KD and GM refer to cell strains developed from the same patient simultaneously but maintained in different laboratories until the assay was performed. NAD represents a different patient.

‡ WJ and TL refer to cell strains developed from the same patient 2 years apart. TL was assayed after the second subculture.

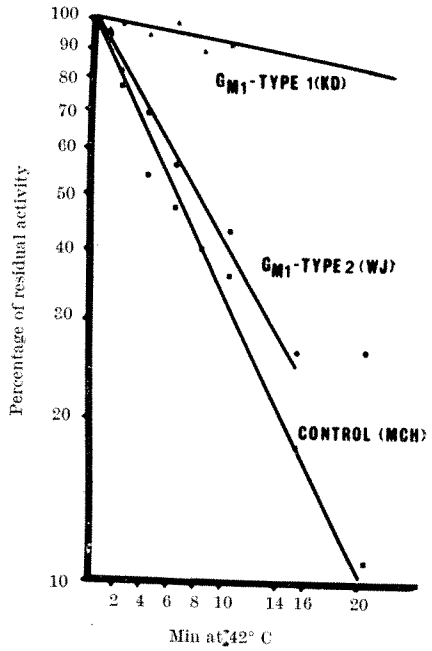

Fig. 2. Thermolability at 42° C of β-galactosidase in fibroblasts of a control and both types of G_{M_1}-gangliosidosis in 0·1 M acetate buffer, *p*H 5·0. Residual activity at each time is expressed as a percentage of initial activity. ▲—▲, G_{M_1}-Type 1; ●—●, G_{M_1}-Type 2; ■—■, control.

We conclude that the two clinical types of G_{M_1}-gangliosidosis are determined by different mutant genes acting to reduce lysosomal β-galactosidase activity, though their precise modes of action remain to be defined. Multiple forms of β-galactosidase have been demonstrated recently within mammalian brain[8], liver[9] and kidney[10] by molecular sieve chromatography or starch gel electrophoresis. The Hurler syndrome seems to be associated with absence of one of these forms in liver[11,12]. It is tempting to suggest that the genes causing each type of G_{M_1}-gangliosidosis differ in terms of their effect on one or more of these forms of β-galactosidase. One difficulty with this approach is that the same form of liver β-galactosidase seems to be absent in three different types of mucopolysaccharide storage disorder: the autosomal recessive Hurler and Sanfillipo syndromes and the *X*-linked recessive Hunter syndrome[12].

To date, five different mutant genes are known to reduce lysosomal β-galactosidase activity in human beings. Comparative studies on cultured fibroblasts expressing one or more of these mutant genes should help to show how these genes act.

Reappraisal of Biological Ageing

LIVING systems depend on adaptive regulation, deterioration in which leads eventually to death. The incidence of most disease increases with increasing age, which suggests that progressive impairment of adaptive response is associated with many illnesses common to advanced age. One biochemical expression of this impairment is the age-dependent increase in the time required to initiate certain enzyme inductions after administration of the appropriate inducing stimulus[1,2] (Table 1).

This biochemical parameter of ageing may provide a unique opportunity to investigate a sequence of events responsible for a particular ageing phenomenon. Recent evidence demonstrated that newly regenerated liver cells in ageing animals exhibit enzyme induction patterns characteristic of untreated animals of the same age[2,10]. So either the age-dependent modification of hepatic enzyme regulation must arise from a genetic alteration of the liver cell which is copied during the cell division

* Unpublished results of R. W. Hanson.

nduced by partial hepatectomy, or it is not inherent in the liver cell. Two independent observations suggest that the latter is the case. The induction of mouse liver tyrosine aminotransferase by exposure to cold, considered an adrenal steroid mediated process, exhibited an age-dependent lag period, whereas enzyme induction after administration of cortisol was independent of age[4]. Similarly, induction of rat liver glucokinase by glucose feeding, an insulin mediated process, exhibited an age-dependent lag, but enzyme induction by administration of insulin was independent of age (R. C. A., unpublished). Thus the ability of liver cells to respond to hormonal stimulation, unlike that of other cell-types such as adipose cells[11], is not an age-dependent phenomenon[2].

The role of endocrine function in the age-dependent modification of hepatic enzyme regulation is not clear. According to Finch *et al.*[4], the production of corticosterone by the adrenal glands in response to exposure to cold is not influenced by age. So the ageing modification involving tyrosine aminotransferase must occur between adrenal steroid production and hepatic enzyme induction. But the procedures available for accurate determination of functional serum hormone levels are questionable at best. An alternative approach recently developed by Adelman (R. C. A., unpublished) entails stimulation of the appropriate endocrine source and determination of circulating, functional hormone production as expressed by the time course of hepatic enzyme induction. Adrenal corticotrophic hormone (ACTH) administration resulted in a rapid, age-dependent increase in hepatic tyrosine aminotransferase activity (Fig. 1). Eighteen-month old rats required approximately twice as much time as 2 month-old rats to respond similarly to the same body-weight dosage of ACTH. If this enzyme induction was hormone mediated, then the endocrine function in question is influenced by age. It seems unlikely, however, that this induction was mediated by adrenal steroid. Whereas tyrosine aminotransferase activity peaked 4–5 h following administration of cortisol, the ACTH effect was observed in as little as 1 h and terminated after 3 h (R. C. A., unpublished). When the endocrine role in the age-dependent modification of hepatic enzyme regulation is resolved, the influence of sympathetic and parasympathetic innervation and of pituitary and hypothalamic function can be examined.

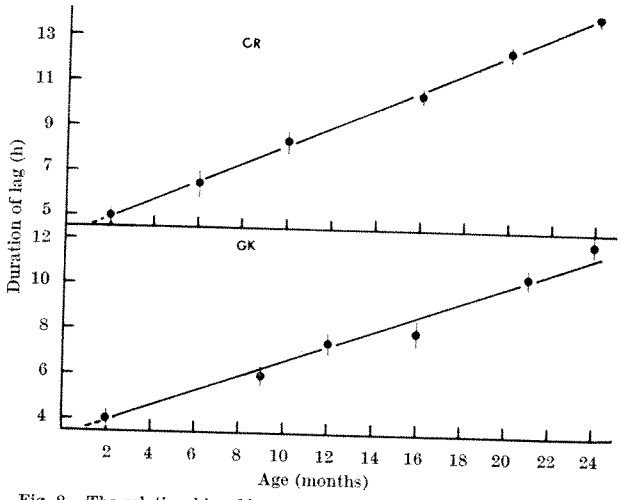

Fig. 2. The relationship of lag period duration of the glucokinase (GK) and NADPH : cytochrome *c* reductase (CR) inductions to chronological age of the rat. Tissue was prepared and enzyme activities assayed as described previously[1,2]. Each value represents the mean ±s.e. for at least four rats.

This general approach not only localizes the tissue of origin of the age-dependent modifications, but also contributes to comprehension of the ageing process(es). The unknown modification which is expressed as an increased lag period of hepatic enzyme induction was observed throughout the entire lifespan of the rat[2]. Looking at the chronological origin of this modification (Fig. 2), it is apparent that the briefest lag period for the inductions of glucokinase[1] and NADPH : cytochrome *c* reductase[2] coincides with the development of adult levels of these enzymes, approximately 15–30 days after birth[12,13]. It is tempting to speculate that the ageing phenomena which are expressed in adult liver and perhaps other tissues are the consequence of developmental phenomena in the foetal neuroendocrine regulatory system.

Inhibition of Chemical Carcinogenesis in the Hamster Cheek Pouch by Topical Chlorpromazine

NUMEROUS studies have shown that chlorpromazine (CPZ) affects the function of biological membranes[1] and the lysosomes[2]. The effect of CPZ seems to be dose-dependent[3,4], but in most studies it caused a decrease in membrane permeability[5,6], and it has been shown to antagonize lysosomal labilization induced by vitamin A[2]. In previous studies, chemical carcinogenesis in the hamster cheek pouch was promoted by the membrane and lysosomal labilizers vitamin A palmitate[7] and stilboestrol diphosphate[8]. We now report the effect of CPZ on the same experimental model.

The right cheek pouches of thirty male Syrian golden hamsters aged 2 months were painted three times per week with one of the following substances dissolved in liquid paraffin: 0·5 per cent 9,10-dimethyl-1,2-benzanthracene (DMBA) (twelve animals, D group); 0·5 per cent DMBA combined with 1·2 per cent CPZ USP (twelve animals, DC group); or 1·2 per cent CPZ (six animals, C group). A further six animals were treated with paraffin only (P group). Half the animals in each group were killed after 9 weeks, and the remainder after 12 weeks. During the macroscopic examination of the cheek pouches, the tumours were counted, and the nature of these lesions was determined histologically. Multiple sections were also taken from macroscopically non-tumorous areas of the cheek pouches. The neoplastic lesions were classified as benign papillomas, intraepithelial carcinomas, papillomas with intraepithelial carcinoma (atypical papillomas), or invasive squamous cell carcinomas, as defined previously[8]. Papillomas and squamous cell carcinomas could be counted accurately. Because intraepithelial carcinomas did not present tumours macroscopically, the frequency of these lesions had to be estimated from multiple histological sections, and the findings were expressed as − when these lesions were not found, as + when only a few of these lesions were present in some animals of a group, or as + + when many lesions were present in each animal. The cheek pouches in the C and P groups were normal. The results in the other groups are summarized in Table 1.

Generally, the cheek pouch mucosa in the DC group showed mild benign epithelial hyperplasia, hyperkeratosis, and marked fibrosis and inflammation of the lamina propria. The striking finding in this group, however, was a very marked suppression of epithelial neoplasia, with almost complete inhibition of carcinoma formation after 9 and 12 weeks.

The promotion of chemical carcinogenesis in the hamster cheek pouch by membrane labilizing agents encountered in previous studies[7,8] was attributed to the known effect of these substances on cell membranes or lysosomes[9,10]. In this study, tumour inhibition was achieved with the membrane stabilizing agent CPZ. A similar inhibiting effect of CPZ on tumorigenesis has been recorded by others[11,12], but the mechanism of this effect has not been ascertained. The effect of CPZ on carcinogenesis may have been due to decreased permeability of cellular membranes, resulting in less effective penetration of the carcinogen into cells and subcellular structures. On the other hand, decreased permeability of subcellular structures induced by CPZ may have resulted in stabiliza-

tion of lysosomal membranes and in decreased liberation of lysosomal enzymes, which may play a part in the early stages of cell division and carcinogenesis[10], particularly because CPZ is also known to suppress DNA synthesis in the bone marrow granulocytic series, resulting in delayed cell division[13].

Fibrin Proteolysis in the Monkey Uterine Cavity: Variations with and without IUD

The uterine tissues of several mammalian species are an abundant source of plasminogen activator[1]. Human menstrual discharge is known to contain high concentrations of plasminogen activator and plasmin but insignificant amounts of fibrinogen and plasminogen[2]. Plasmin, the product of plasminogen activation, proteolytically degrades fibrin and fibrinogen preferentially to other substrates; so a likely physiologic role of plasminogen activator in the uterus would be that of maintaining menstrual blood in a fluid state.

During menstruation, when necrotic endometrial tissue releases its store of activator into the plasminogen rich environment of intrauterine blood, intense fibrinolysis (and fibrinogenolysis) is predictable. The role and magnitude of fibrinolytic activity in the uterus between menses, however, are not clear. During the normal intermenstrual period, endometrial cells are morphologically intact and may not release plasminogen activator. Research on fibrinolytic activity in the cavity or endometrium of the uterus between menses has been hampered by difficulties in collecting adequate quantities of unaltered cavitary fluid or endometrial tissue from unanaesthetized living organisms. Moreover, quantitative fibrinolytic assays on tissue generally do not differentiate between plasmin activity generated by tissue factors and that generated by factors in the blood contained within the tissue. The extraction procedure of Astrup[3], performed on endometrium followed by assay of plasminogen activator, does not necessarily reflect actual plasmin activity *in vivo*; rather it is a measure of the potential for plasmin activity. Fibrinolytic activity other than that of plasmin has apparently been measured in endometrium between menses[4], but the role and extent of such activity *in vivo* are not clear. This report describes preliminary studies of local fibrin proteolysis in the intermenstrual monkey uterus.

In order to investigate *in vivo* proteolytic behaviour, we have used intrauterine incubations of 'Millipore' chambers containing radioactive fibrin. These chambers have a mean pore size of 0·45 μm and have the following properties: they allow free interchange between uterine fluid and chamber of soluble molecules (including proteolytic enzymes, their precursors, and fibrin degradation products); they contain insoluble fibrin polymers; and they exclude cells which might attack fibrin phagocytically. Thus the percentage loss of radioactivity from these chambers following intrauterine incubation was used as an index of proteolytic activity. Because of our interest in the effect of intrauterine contraceptive devices, some incubations were performed on animals wearing such devices (modified Lippes loops).

One preparation of lyophilized ^{125}I-labelled fibrin was used for all experiments (unpublished results of R. W. C. and S. T. S., jun.). This preparation was insoluble in 5 M urea and free of any significant amount of active plasmin, plasminogen, plasminogen activator or other fibrinolytic activity. Each cylindrical 'Millipore' chamber, measuring 1·9 × 13·0 mm, was packed loosely with 10 mg of the fibrin preparation, sealed with silicone rubber, and then hydrated for 2 h in *p*H 7·0 buffer (0·033 M phosphate–0·075 M NaCl) before uterine insertion. *In vitro* experiments on representative chambers showed good retention of fibrin, complete exclusion of red cells and leucocytes from the chamber interior and response to plasmin and trypsin by progressive loss of chamber radioactivity. Degradation of fibrin was not produced by trauma to the chambers as long as there were no grossly visible tears in the nylon backed 'Millipore' membrane. Unanaesthetized, ovariectomized *Macaca mulatta* monkeys artificially cycled with oestradiol and progesterone were used. All animals had chronic surgical fistulas connecting the anterior abdominal surface with the uterine cavity. The fistulas served as a convenient route for accurate insertion of chambers and intrauterine devices. These preparations have been described previously[5,6]. In all cases, the fibrin-containing 'Millipore' chambers were inserted on the twenty-first day of a 24 day menstrual cycle and extracted 18 h after insertion. Chambers were washed in buffer after extraction to eliminate diffusible fibrin degradation products. Determinations of chamber radioactivity were then made in a well-type scintillation spectrometer. Conditions of sample geometry and counting which would assure valid comparisons between chambers were established and maintained. Loss of radioactivity from the chamber over the 18 h incubation was expressed as "per cent lysis" and calculated as follows

$$\text{per cent lysis} = \frac{(C_1 - C_2)\ 100}{C_1}$$

where C_1 = net c.p.m. in chamber before insertion; C_2 = net c.p.m. in chamber after extraction and washing.

Table 1. LYSIS OF FIBRIN IN THREE CONDITIONS OF INCUBATION

Incubation (N)*	Per cent lysis Mean	s.d.
In vitro group (60)	6·1	1·6
In utero group (37)	32·9	10·2
In utero—IUD group (10)	56·7	8·0

* Incubation was for 18 h in all cases. N designates the number of incubations in each group. In the *in utero* groups, N represents the number of animal cycles satisfactorily tested.

Table 1 summarizes the data for three experimental groups. The first group consists of sixty control chambers incubated simultaneously with *in utero* experiments in *p*H 7·0 phosphate–saline buffer at 37° C with gentle agitation. The degree of fibrin lysis measured under these *in vitro* conditions was consistently low with a mean of 6·1 per cent and a standard deviation of 1·6 per cent. In the second group, proteolysis was measured during thirty-seven cycles in eighteen monkeys without intra-

uterine devices. Mean per cent lysis for this group was 32·9 per cent. In the third experimental group, lysis measured during ten cycles in seven monkeys with an intrauterine device (IUD) was 56·7 per cent. The difference in proteolytic activity between the IUD and non-IUD monkey cycles is statistically significant ($P < 0.001$). (Although the compared sample groups appear to be homoscedastic (F test) and results from the t test are significant ($P < 0.001$), the size of the sample population is so small that we have relied on the non-parametric Mann–Whitney U test.) An analysis of intercyclic variation in individual monkeys was done in order to further evaluate possible differences in proteolytic activity caused by intrauterine devices. For this purpose the differences in per cent lysis between cycles were divided into two groups: all consecutively measured cycles without an IUD in individual animals, and all consecutively measured cycles in which an animal wore an IUD during one cycle but not during the other. Data from which these differences are calculated are shown graphically in Fig. 1. Intercyclic differences for the two groups are plotted in Fig. 2. Mean difference in per cent lysis between consecutively measured cycles without an IUD was 6·8 per cent. Nineteen such intercyclic differences in ten monkeys varied from 0·3 to 16·9 per cent lysis. Mean difference between consecutively measured cycles with and without an IUD in individual monkeys was 22·3 per cent lysis. Five such intercyclic differences in four monkeys ranged from 13·4 to 34·9 per cent. The variation in proteolytic activity between the two groups is different statistically ($P < 0.001$).

Harpel and coworkers[7] have measured fibrinolytic activity of mouse uterine fluid after collecting the fluid from distended uterine horns after cervical ligation. They indicated that there is no direct proteolytic effect on fibrin from non-haemorrhagic cavitary fluid of mice. Plasminogen activator has been observed histochemically

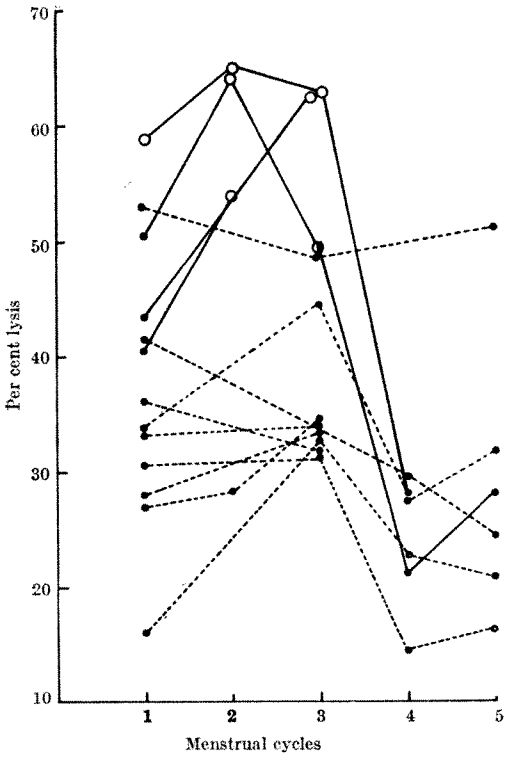

Fig. 1. Per cent lysis of fibrin following 18 h incubation *in utero*. Each incubation begins on the twenty-first day of the menstrual cycle. Open and closed circles represent per cent lysis values while solid and broken lines connect consecutive measurements on individual animals in the following manner: ○, IUD present during cycle measured; ●, IUD not present during cycle measured; —, IUD present during one or more cycles; - - - , IUD not present during any cycles.

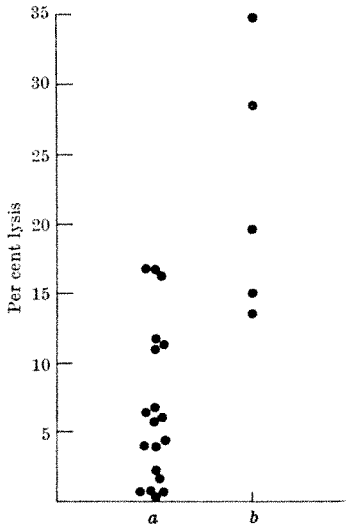

Fig. 2. Intercyclic differences in per cent lysis in (*a*) consecutively measured cycles without an IUD, and (*b*) consecutively measured cycles with and without an IUD.

by other investigators[8,9] in the surface epithelium ar stromal vessels of intact human and rat endometriur but little plasmin or other direct fibrinolytic activity this tissue between menses has been inferred from su techniques. Our work demonstrates direct, and qui active, fibrin proteolysis in the intermenstrual monk uterus.

Because of uncontrolled variables inherent in an *in vi* proteolytic assay, our measurements have probably n quantified enzyme activity in a linear fashion. Tl measurements we have made, however, should rela levels of greater or lesser activity among animal cycle for the same quantity of initial substrate and the san time of incubation were used for each animal cycl Biopsies of endometrium taken immediately after chamb extraction were studied microscopically for histolog alterations caused by the chambers themselves. Althou intracavitary leucocytosis was stimulated, the end metrium was not significantly affected. The possibili that fibrin proteolysis was stimulated primarily l chamber insertion will be investigated in future work.

Several sources of the proteolytic activity we ha measured seem possible. Plasma proteases could enter tl uterine cavity by diffusion from endometrial capillarie Such enzymes could also be released from leucocytes the superficial endometrium or uterine cavity. Perhaps more interesting possibility is the release of plasminog activator from endometrial sources such as the lini epithelium or vascular endothelium. If plasminogen present in the plasma transudate of endometrium ar uterine cavity, plasmin activity could be generated either site by plasminogen activator. Regardless of t characteristics and origin of proteolysis, however, flu in the intermenstrual uterine cavity of monkeys c digest fibrin, and this capability appears to be enhanc by the presence of a plastic intrauterine device.

We thank Dr R. M. Nakamura for advice on statistic analysis. This investigation was supported by a grant fro the Ford Foundation.

Peroxide Production by Mycoplasmas in Chicken Tracheal Organ Cultures

MANY mycoplasmas liberate peroxide *in vitro*[1-3] and this might be an important virulence factor in respiratory infections[1,3,4]. There are, however, few *in vivo* data[5] to support this hypothesis. Recently we showed that several mycoplasma species grew in chicken embryo tracheal organ cultures and that some adversely affected ciliary activity[6]. Subsequent studies have shown that the cytopathic effect of *M. mycoides* var. capri in organ cultures is caused by peroxide secretion[7]. Conversely, damage to cilia caused by *M. gallisepticum* is not (unpublished observations of J. D. C. and D. T-R.). We have now measured and compared peroxide production by several mycoplasmas in tracheal organ cultures and correlated the findings with damage to the ciliated epithelium.

Chicken embryo tracheal organ cultures were prepared as described elsewhere[6]. A group of five cultures was used for each factor investigated. Peroxide was measured by a modification of the aminotriazole–catalase method[8]. In this, catalase combines with hydrogen peroxide to form a complex which then reacts with aminotriazole, so irreversibly inhibiting catalase activity. Because this occurs only when hydrogen peroxide is present, the reaction is a specific test for this molecule. The rate of catalase inhibition is proportional to the rate of hydrogen peroxide secretion, and we have expressed the results not as absolute amounts of peroxide but as a percentage reduction of catalase activity from that originally present. Beef liver catalase (0·2 mg Boehringer), and aminotriazole (3·5 mg Koch Light), were added to organ cultures inoculated 3 to 5 days previously with mycoplasmas. Initially, and at convenient intervals thereafter, 0·05 ml. aliquots were removed from each of five tubes within an experiment group and pooled. To 0·1 ml. of harvested pooled medium was added 0·5 ml. of 2 per cent ethyl alcohol to stop the reaction, the mixture incubated at room temperature for 10 min and diluted to 10 ml. with distilled water. Residual catalase activity was determined by a permanganate titration method[9].

Table 1. THE REDUCTION (PER CENT) IN CATALASE ACTIVITY AFTER INCUBATION OF TUBES WITH AND WITHOUT CHICKEN TRACHEAL SECTIONS MAINTAINED IN MEDIA CONTAINING CATALASE OR CATALASE-AMINOTRIAZOLE (AT)

Duration of incubation (days)	Medium containing catalase and tracheal sections	Medium containing catalase	Medium containing catalase-AT and tracheal sections	Medium containing catalase-AT
1	12	3	62	41
4	35	47	100	100
8	43	47	—	—

We first investigated the stability of catalase and catalase-aminotriazole in the organ culture system. More than 50 per cent of the catalase remained active for at least 8 days in culture tubes whether or not they contained tracheal ring sections (Table 1). Conversely, tubes containing tracheal sections and catalase–aminotriazole lost 62 per cent of their catalase activity in one day and tubes without sections lost 41 per cent of their catalase activity over a similar period. The culture medium therefore contained a substance which on incubation generated peroxide. Because cultures with tracheal sections, in three experiments, lost more catalase activity than cultures without sections it seemed that peroxide was produced by the tracheal rings as well as by the medium.

Table 2. THE COMPARATIVE GENERATION OF PEROXIDE BY SELECTED MYCOPLASMAS, AND TRACHEAL SECTIONS IN THE CHICKEN TRACHEAL ORGAN CULTURE SYSTEM

Duration of incubation (h)	*M. mycoides* var. capri	*M. mycoides* var. mycoides (strain Gladysdale)	*M. gallisepticum* (strain MG2)	*M. gallinarum* (strain W115)	Uninfected culture
4	32				
6	41				
24	98	13	41	10	37
72	100	100	100	86	75

Peroxide is expressed as percentage reduction of catalase activity inhibited. The concentration of each mycoplasma in the medium was 10^7 c.c.u/ml. at time 0 h. Results were obtained in one experiment.

Peroxide generated by several mycoplasmas, including *M. mycoides* var. capri (henceforth called *M. capri*), was measured over a period of time (Table 2). *M. capri* produced peroxide rapidly, virtually all catalase activity being inhibited by hour 24. At this time, some of the other mycoplasma-infected cultures had produced even less peroxide than the uninfected cultures. At hour 72, however, cultures infected by *M. mycoides* var. mycoides and *M. gallisepticum* had produced sufficient peroxide to inhibit all catalase activity, whereas 25 per cent activity still remained in the control cultures. In other experiments (Table 3), only cultures infected with *M. capri*, and the related strain B3, clearly produced more peroxide than uninoculated cultures. Because many of the other mycoplasmas tested liberate peroxide *in vitro*[2] it is surprising that when they were present in the organ culture system we could not demonstrate more peroxide than the greatest amount produced by the tracheal cultures themselves.

Cohen and Somerson[10] noted that the rate of peroxide generation by *M. pneumoniae* was proportional to the number of organisms. The difference in peroxide production between *M. capri* and the other species we investigated was not merely a function of organism concentration. The number of organisms of *M. mycoides* var. mycoides or *M. gallisepticum* (MG2) in the organ cultures was equal to or greater than *M. capri* (Table 3).

Table 3. THE GENERATION OF PEROXIDE BY SELECTED MYCOPLASMAS FOLLOWING GROWTH FOR ONE DAY IN CHICKEN TRACHEAL ORGAN CULTURES

Mycoplasmas and control cultures	Concentration of mycoplasmas c.c.u./ml. of medium	Catalase inhibited (per cent)
M. capri (average of 4 experiments)	10^7	97 (range 89–100)
B3 strain	10^8	83
M. mycoides var. mycoides (Gladysdale) (average of 3 experiments)	10^7	38 (range 13–62)
M. mycoides var. mycoides (T3)	10^8	57
M. gallinarum (W115) (average of 2 experiments)	$10^{8.5}$	9 (range 7–10)
M. gallisepticum (J1)	10^8	17
M. gallisepticum (MG2)	10^7	41
WR1 strain	10^5	45
M. pulmonis (M1)	10^5	33
M. pneumoniae (FH)	10^9	58
M. hominis (73T)	10^8	46
M. laidlawii B	10^8	57
Uninoculated control cultures (average of four experiments)		38 (range 5–62)

Peroxide is expressed as percentage reduction of catalase activity inhibited. The results were obtained from several experiments.

The relationship between mycoplasma peroxide generation and damage of ciliated tracheal epithelium is dependent on many factors. These include the quantity of hydrogen peroxide produced, its delivery to the cellular site, and its effect on the mycoplasmas liberating it. Tissue cell and microbial organism catalase[11] and organism peroxidase[10] must also be considered when evaluating the ultimate results in organ culture or *in vivo*. Of the

mycoplasmas studied, only *M. capri*, strain B3, and the *M. gallisepticum* strains cause rapid ciliary damage of chicken tracheal organ cultures. The damage caused by *M. capri*, which produces a large amount of hydrogen peroxide, can be delayed by adding catalase to the organ culture system, whereas the damage by *M. gallisepticum*, which does not produce a measurable amount of peroxide in the system, cannot be reversed by adding catalase. These findings suggest that peroxide is an important virulence factor in *M. capri* infections, but that a different mediator or mediators should be searched for in *M. gallisepticum* disease.

Metabolism of D-Alanine in *Rhodospirillum rubrum* and its Bacilliform Mutants

THE photosynthetic bacterium *Rhodospirillum rubrum* affords a particularly simple and versatile system for study of variability in bacterial form. Its morphology

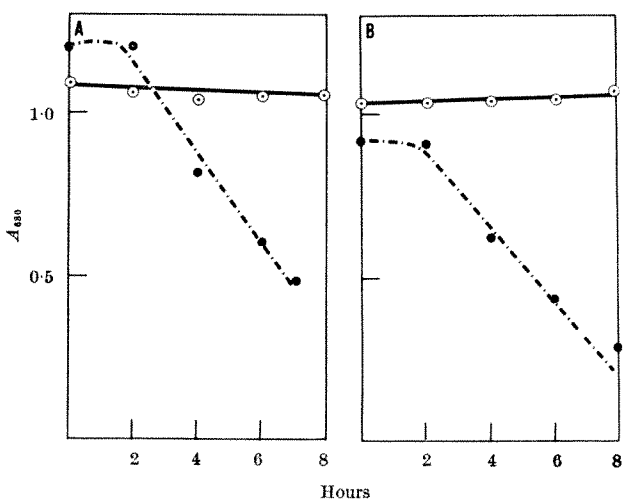

Fig. 1. Lysis of logarithmic phase cells by cycloserine. Strains used were parent *Rhodospirillum rubrum*; strain S_4; a bacilliform mutant; strain S_{10}, another bacilliform strain; and S_4R_1, a spiral revertant of S_4. Cycloserine, 5 μg/ml. added at 0 time, and absorbance of cultures measured at 680 nm (where pigment absorption is minimal). All cultures grown anaerobically in the light in a malate medium[18]. $A.S_4$ bacillus: ○—○; parent spirillium: ●—·—·—●. $B.S_{10}$ bacillus: ○—○; S_4R_1 spiral revertant: ●— — ·—·—●.

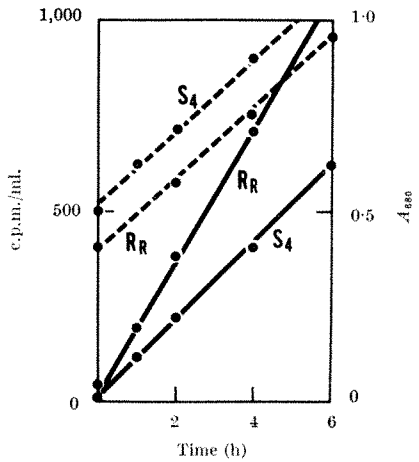

Fig. 2. Incorporation of D-alanine-^{14}C (2 μmoles/ml., 16,500 c.p.m./μmole) into wall fraction by parent spirillum R_R, and bacilliform strain S_4. Alanine added at 0 time to logarithmic phase cultures and the absorbance at 680 nm (●- - -●) and radioactivity incorporated into phenol insoluble (wall fraction) was measured (●—●).

can be altered by nutritional, genetic or chemical means. In addition to spirilla, this organism readily forms rods, vibrios, filaments, circular cells, chains of rods and chains of spirilla[1–3]. Many of these variants have one feature in common: they can be induced either by D-alanine or agents which affect D-alanine metabolism. D-Alanine is a main constituent of bacterial cell walls[4], and the dipeptide derived from it is essential for the terminal cross-linking step in cell wall synthesis[5–9].

It was shown earlier that the wall of curved forms of *R. rubrum* is more extensively cross-linked than that of bacilliform cells, indicating one of the effects of morphological mutation from spirillum to rod. Based on this finding and others, it was postulated that bacilliform mutants were defective in D-alanine synthesis (that is, leaky mutants)[10]. Accordingly, further aspects of D-alanine metabolism in *R. rubrum* have been examined. Evidence is presented for a difference in D-alanine metabolism in parent and mutant strains.

The antibiotic D-cycloserine, an analogue of D-alanine, is a competitive inhibitor of alanine racemase and D-alanyl–D-alanine synthetase[11–14]. Most bacteria are sensitive to this antibiotic and the effects of cycloserine are reversed by D-alanine[15–17]. When added to culture media at sublethal concentrations, cycloserine will convert *R. rubrum* into a vibrio form. At lethal concentrations, cycloserine lysed log phase cells of *R. rubrum* but not stationary phase cells, and this lysis was inhibited by D-alanine. The antibiotic therefore appears to create a lethal unbalanced growth situation[18]. If lysis of *R. rubrum* by cycloserine requires active cell-wall synthesis, treatment with this antibiotic should serve as a sensitive indicator of how much D-alanine the cells need for wall synthesis and cross-linking. A comparison was therefore made of the lytic effect of D-cycloserine on spiral and bacilliform *R. rubrum* strains. The data show that at a lethal concentration of cycloserine, spiral cells are much more sensitive to lysis by this agent than are bacilliform cells (Fig. 1). This result would be expected in a cell making a tightly cross-linked wall, and, consequently, having a greater demand for D-alanine to form precursors for wall closure. At higher cycloserine concentrations, both cell types were lysed; the spirillum at a faster rate.

Assimilation of D-^{14}C-alanine into cell walls of parent and mutant strains was then compared using log phase cultures. The parent spirillum did incorporate more D-alanine into wall material in growth conditions comparable with that of bacilliform cells (Fig. 2).

These results therefore lend support to the hypothesis proposed earlier, that the morphology of *R. rubrum* can be related to the ability of the organism to synthesize

D-alanine necessary to form the requisite precursors for cell-wall cross-linkage. An unbalanced growth situation with respect to D-alanine, whether created genetically or nutritionally, can either alter the morphology of viable cells or, if severe enough, cause lysis. An analogous situation may exist in the L-forms of bacteria in which the levels of wall intermediates are low or nondetectable[20].

Effect of Ca^{2+} on the Water and Non-electrolyte Permeability of Phospholipid Membranes

THE study of the effect of Ca^{2+} ions on phospholipid membranes by Tobias *et al.*[1-3] has chiefly been devoted to electrical properties and ion fluxes in relation to the hypotheses concerning the axon shifts from the resting to the excited state[4]. Although Leitch and Tobias[2] have shown that Ca^{2+} also induces great changes in the osmotic water flow across these membranes, little attention has been paid to this particular aspect of their behaviour. This report is a study of the modification of the water and non-electrolyte permeability of phospholipid membrane under the influence of calcium. The results obtained suggest the possible role of this ion in the control of cell membrane permeability to non-ionic species.

Phospholipid membranes were made by impregnating 'Millipore' filter disks (estimated pore radius: 250 Å) with 'Cephalin' (Nutritional Biochemicals Co.) as described by Tobias[1]. The membranes were equilibrated for 1 h in either water, NaCl (100 mM) or $CaCl_2$ (50 mM) solutions. The following average composition was obtained: 'Millipore' cellulose material: 7 mg/cm², and cephalin: $2{\cdot}0 \pm 0{\cdot}1$ mg/cm². The water content, measured by drying *in vacuo* at room temperature, was $7{\cdot}5 \pm 0{\cdot}2$ mg/cm² after equilibration in water, $7{\cdot}35 \pm 0{\cdot}2$ mg/cm² in NaCl, and $7{\cdot}1 \pm 0{\cdot}2$ mg/cm² in $CaCl_2$.

The membranes were clamped between two lucite chambers. The hydraulic conductivity, L_p, and diffusion coefficients, ω, for water (^{3}HHO) and for ^{14}C-labelled non-electrolytes were measured in the three media according to methods described elsewhere[5]. Preliminary experiments having shown that 'Cephalin' is not washed out by low pressure (the membranes lose less than 10 per cent of their 'Cephalin' content after 24 h under 40 cm of Hg), L_p was measured under hydrostatic pressures of up to 20 cm of Hg and was found constant for several hours. Hydraulic conductivities, L_p, and water (^{3}HHO) diffusion coefficients, $\omega_{^3HHO}$, were measured on membranes successively placed in water, NaCl and $CaCl_2$ solutions. There are only slight differences in L_p and $\omega_{^3HHO}$ between water and NaCl (Table 1). On the other hand, there is a 100-fold decrease in L_p and a two-fold decrease in $\omega_{^3HHO}$ in $CaCl_2$ solution as compared with NaCl solution. This effect of calcium is reversible. It appears that Ca^{2+} induces an important reorganization of the membrane 'Cephalin'–water medium which takes place without significant changes in composition. It is convenient to translate the phenomenon in terms of membrane porosity and pore radius. Membrane porosity, as measured by the ratio $g = L_p / V_w \omega_{^3HHO}$ (in which V_w is the water molar volume) undergoes a fifty-fold decrease, and the equivalent pore radius of the 'Cephalin' membranes which may be computed from the relation $g = 1 + r^2 RT / 8\eta \bar{V}_w D_w$ (in which η and D_w are respectively the viscosity and the self diffusion coefficient of water) decreases from about 80 Å in NaCl to 12 Å in $CaCl_2$. It must, however, be kept in mind that this simple geometrical translation cannot be taken as a full interpretation of the structural change observed.

Table 1. HYDRAULIC CONDUCTIVITY AND WATER DIFFUSION COEFFICIENTS OF MEMBRANES IN WATER, NaCl AND $CaCl_2$

	Water	NaCl (100 mM)	$CaCl_2$(50 mM)
$L_p \times 10^{11}$ (cm³ dyne^{-1} s^{-1})	$1{\cdot}6 \pm 0{\cdot}1$	$1{\cdot}4 \pm 0{\cdot}1$	$0{\cdot}013 \pm 0{\cdot}003$
$\omega \times 10^{15}$ (mole dyne^{-1} s^{-1})	$2{\cdot}0 \pm 0{\cdot}15$	$1{\cdot}80 \pm 0{\cdot}13$	$0{\cdot}75 \pm 0{\cdot}05$
$g = L_p / V_w \omega_{^3HHO}$	435 ± 5	428 ± 5	$10 \pm 1{\cdot}5$

These figures are the averages obtained from data on five different membranes. In spite of the relatively large variation from membrane to membrane, g values are remarkably constant.

Table 2. DIFFUSION COEFFICIENTS OF NON-ELECTROLYTES

	NaCl (100 mM)		$CaCl_2$ (50 mM)		ω_{CaCl_2}
	K_s	$\omega \times 10^{15}$	K_s	$\omega \times 10^{15}$	ω_{NaCl}
Water	1	$1{\cdot}80 \pm 0{\cdot}1$	1·0	$0{\cdot}76 \pm 0{\cdot}05$	$0{\cdot}41 \pm 0{\cdot}02$
Ethanol	$1{\cdot}55 \pm 0{\cdot}02$	$1{\cdot}48 \pm 0{\cdot}1$	$1{\cdot}54 \pm 0{\cdot}02$	$0{\cdot}49 \pm 0{\cdot}05$	$0{\cdot}33 \pm 0{\cdot}01$
sec-Propanol	$1{\cdot}84 \pm 0{\cdot}02$	$1{\cdot}30 \pm 0{\cdot}1$	$1{\cdot}86 \pm 0{\cdot}02$	$0{\cdot}37 \pm 0{\cdot}03$	$0{\cdot}28 \pm 0{\cdot}005$
Formamide	$1{\cdot}31 \pm 0{\cdot}02$	$0{\cdot}90 \pm 0{\cdot}05$	$1{\cdot}31 \pm 0{\cdot}02$	$0{\cdot}14 \pm 0{\cdot}01$	$0{\cdot}16 \pm 0{\cdot}005$
Acetamide	$1{\cdot}40 \pm 0{\cdot}02$	$0{\cdot}60 \pm 0{\cdot}05$	$1{\cdot}39 \pm 0{\cdot}02$	$0{\cdot}059 \pm 0{\cdot}005$	$0{\cdot}10 \pm 0{\cdot}005$

These figures are the averages obtained from four sets of data on four different membranes. In spite of the relatively large variations from membrane to membrane, the ratio $\omega_{CaCl_2}/\omega_{NaCl}$ for a given solute seems remarkably constant.

Table 2 lists the diffusion coefficients, ω, of water and four small non-electrolytes—ethanol, *sec*-propanol, formamide and acetamide—measured successively in NaCl and $CaCl_2$ solutions. In every case, ω is markedly smaller in $CaCl_2$ than in NaCl. The ratios $\omega_{CaCl_2}/\omega_{NaCl}$ decrease with the solute size. Furthermore, this ratio is two to three times lower for amides than for alcohols. The solute partition coefficients K_s, measured between the membrane water and the water of the bathing solutions, are listed in columns 2 and 3 of Table 2. There are no significant differences between the K_s measured in NaCl and $CaCl_2$ solutions. The effect of calcium on ω cannot be ascribed to a diminution of the solute K_s and must therefore be related to the decrease in the radius of the aqueous paths. The great difference in sensitivity to the change in a geometrical parameter of amide and alcohol diffusion may be explained by two considerations: because of their greater lipid solubility, alcohols exhibit higher K_s than amides. This could partially explain the small sensitivity of alcohols, which can diffuse both through water and lipids. The computation of the frictional coefficients, however, which takes into account the partition coefficient, shows that a difference in lipid solubility alone cannot account for the phenomenon

observed. The difference in the behaviour of amides and alcohols is more completely explained by the different hydrogen-bonding ability of the two chemical functions. It has been shown[5] that the diffusion rate of non-electrolytes decreases with their increasing H-bonding ability. This effect is greater in dense membranes, in which the solute-membrane frictions are the preponderant factor controlling the diffusion, than in more porous membranes, in which solute–water frictions, less sensitive to H-bonding, predominate.

The effect of Ca^{2+} on the phospholipid membrane model suggests that this ion may have an action not only on ionic permeability, as shown in particular by Whittam[6], but also on water and non-electrolyte permeability. The model seems particularly relevant to the study of specialized cells such as the epithelial cells of the urinary bladder. The 'Cephalin model' mimics remarkably well the great permeability changes observed in this structure under the influence of neurohypophyseal hormones. Leaf and Hays[7,8] have shown on the toad bladder that these hormones produce a forty-fold increase in the L_p of the luminal membrane of the cells and only a 70 per cent increase in water diffusion. Furthermore, the increase of the diffusion rate of non-electrolytes under the influence of the hormones depends critically on their chemical nature, and is much greater for amides than alcohols[8]. Leaf and Hays[8] and more recently Hays[9] have proposed a model based on a system of two barriers in series, in order to explain their findings on the toad bladder. On the basis of the present results, however, it may be considered that the great porosity change of a single barrier can influence the diffusion of non-electrolytes in a selective way according to their chemical function. In addition, the action of Ca^{2+} on phospholipid membrane models suggests the possibility that a molecular mechanism comparable with the shift from the resting to the excited state of axon membranes will apply in the case of these great permeability changes induced by hormones. Experiments are in progress to test this possibility.

Effects of Salts and *p*H on Fish Chemoreceptor Responses

SEVERAL studies have been reported on the effect of *p*H on the taste responses to salt and other taste stimuli in different species. It is suggested that *p*H dependent receptors exist for NaCl[1–3]: in the case of rat and blowfly, the response to NaCl tended to be inhibited below *p*H about 3. I demonstrate here that addition of NaCl or other salts at relatively weak concentrations to HCl solutions increases the response of carp (*Cyprinus carpio*) palatal chemoreceptors.

The summated responses of multifibre strands of the palatine nerve supplying the palatal chemoreceptors were recorded from eleven preparations, using a technique described previously[4]; the stimuli were mixed solutions containing 0·05 M NaCl and varying concentrations of HCl. In each preparation, application of 0·05 M NaCl elicited a very small response. Its magnitude was a fifth of that, for example, of 0·001 M HCl or even smaller. Addition of NaCl at the same concentration to 0·001 M HCl, however, resulted in an enhancement of the response, the magnitude of the response being on average 1·9 times as large as that for the single acid solution. The effect of NaCl was tested also for 0·0005, 0·0025, 0·005 and 0·01 M HCl, and it was found that the combined effectiveness was strongest between 0·001 M to 0·0025 M HCl concentrations, yielding a saturation response–concentration curve in each preparation similar to that illustrated in Fig. 1. The effect of varying concentrations of NaCl is also shown. The magnitude of the response to each of the mixed stimuli containing different quantities of NaCl approaches that for a single acid solution as the concentration of the HCl in each solution is raised to 0·01 M. At this molarity all the curves for these stimuli attain the same magnitude, within experimental error, though they show differences at lower concentrations of HCl. In general, a further increase in concentration did not bring about marked increase in magnitude of the response to the single HCl solution; in this, the carp differs from the rat[5]. In some fish including the carp, it is known that there exist in the palatal or facial chemoreceptor system specific receptors responsive to a limited dilute concentration range of electrolytes (refs. 6 and 7, and I. H. and T. Ogawa, unpublished data). It was therefore suspected that the concentrations of HCl used here might stimulate this specific receptor. It has also been shown that this specific receptor system is depressed by dilute concentration of divalent salts, such as $CaCl_2$ and $MgCl_2$, or by relatively concentrated monovalent salt; solutions for example, about 0·01 M or higher concentrations of NaCl[6,7]. Consequently, the effect of 0·0005 M $CaCl_2$ in varying concentrations of HCl was investigated in five preparations. No noticeable depression of the response was observed over the concentration range of HCl (Fig. 1). $CaCl_2$ also showed an enhancing effect close to that of NaCl of the same normality (for 0·001 M HCl, see Table 1). By contrast with the results with 0·0025 M NaCl, 0·0005 M $CaCl_2$ did not influence the response very much. $CaCl_2$ by itself at the same concentration did not elicit a noticeable response, so it may be concluded that the participation of the specific receptor system in the summated response to HCl was little,

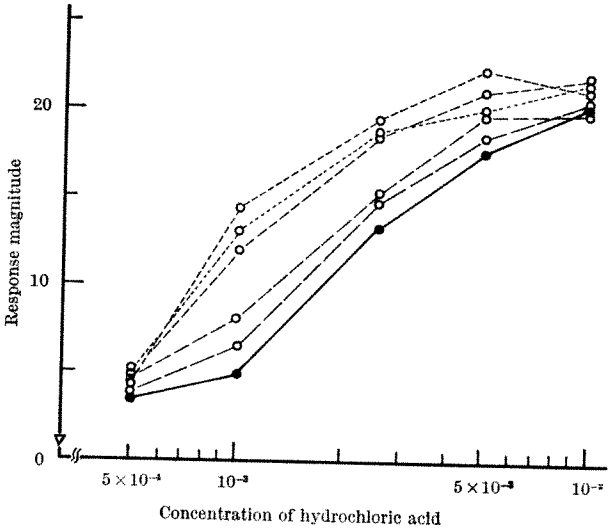

Fig. 1. Summated responses of the carp palatine nerve to mixed solutions of HCl with 0·0005 M $CaCl_2$, and with varying concentrations of NaCl plotted in arbitrary units against molar concentration of HCl. The response to 0·2 M NaCl is also shown (▽). ●—●, HCl; ○——○, HCl+0·0005 M $CaCl_2$; ○— — —○, HCl+0·0025 M NaCl; ○– – –○, HCl+0·0125 M NaCl; ○ · · · ○, HCl+0·05 M NaCl; ○· · · ·○, HCl+0·2 M NaCl.

if any. Thus the results suggest that the enhancement of the response by NaCl—by itself very weak in stimulative effectiveness over the concentration range used—may be related to the activity of the acid receptor rather than the salt receptor.

Table 1. EFFECTIVENESS OF VARIOUS SALTS IN HYDROCHLORIC ACID SOLUTION ON THE CARP CHEMORECEPTOR

Salts	Response to HCl + salt	Salt	Salts	Response to HCl + salt	Salt	Salts	Response to HCl + salt	Salt
NaCl	1·7	0·2	KCl	1·7	0·2*	Na_2SO_4	0·9‡	0·2
NaBr	1·7	0·2	LiCl	1·8	0·2*	$MgSO_4$	1·0‡	0·2*
$NaNO_3$	1·5	0·2	RbCl	1·7	0·2*	$MgCl_2$†	2·0	0·3*
$NaClO_4$	1·5	0·3	Choline-Cl	1·9	0·3	$CaCl_2$†	1·9	0·4*
			NH_4Cl	1·9	0·3*			

* Mean for two preparations.
† Data are presented for 0·025 M.
‡ 0·0025 M HCl; pH = 3·0.

Magnitude of summated responses to 0·001 M HCl + 0·05 M salts and to 0·05 M salts expressed relative to that to 0·001 M HCl. Mean values for three preparations.

Similar enhancements were observed with several chloride salts having different monovalent or divalent cations and sodium salts of different monovalent anions (Table 1). Na_2SO_4 and $MgSO_4$ did not enhance the response over the concentration range of HCl 0·0005 M to 0·01 M. The pHs of the mixed stimuli containing 0·05 M Na_2SO_4 or $MgSO_4$ were found to be slightly higher than those of the corresponding single acid solutions (by a factor of 0·2–0·3); for example, the pH of the mixture containing 0·0025 M HCl and 0·05 M Na_2SO_4 or $MgSO_4$ was nearly the same as that of the single HCl solution at 0·001 M. Both the solutions yielded close response magnitudes as seen in the table. These results do not show whether the enhancement arises from cation or anion effects (except for the sulphate). But some of these salts differ in their effectiveness in salt receptor stimulation, especially when salts with different cations are used[8–12]. To distinguish between effects on the two sorts of receptor, experiments with single fibres were carried out. Fibres were found which did not respond well to NaCl but responded to its mixed solutions with HCl of various concentrations in spike frequencies higher than those noted in responses to each of the single solutions (Fig. 2).

I thank Professor John E. Bardach, University of Michigan, for critical reading of the manuscript. This work was supported by a research grant from the Japan Ministry of Education.

Unusually High Taste Acuity for Phenylthiocarbamide in Two Formosan Aboriginal Groups

FOR this study of acuity of taste for phenylthiocarbamide (PTC), 100 individuals were selected from each of two aboriginal groups living in Taiwan: the lowland-dwelling Ami, and a branch of the Atayal. Acuity was measured by asking the subject to discriminate between distilled water and a PTC solution in a sorting test in which the probability of a correct answer from guessing was 0·125[1]. The solutions comprised a series integrally numbered from zero, solution n containing $2{\cdot}60 \times 2^{-n}$ g PTC/l. The highest value of n at which the subject could still taste the PTC was called his DSN (discriminated solution number) and a continuity correction of +0·5 yields the most likely value for the threshold. We also corrected for the effects of age and sex, taking the 32 year old male as standard subject[1]. Most of the subjects we used were schoolchildren, which meant age-effect corrections lay mostly between −0·7 and −1·3.

Few of the Ami or Atayal subjects had DSNs of less than 6 and many were of 19 and over. This has been found for several other Mongoloid groups, presumed "pure", from which samples of fifty individuals have been tested[2,3]. But whereas in these other samples the incidence of these high DSNs ranged from 4 per cent to 12 per cent, it was 17 per cent in the Ami sample and 30 per cent in the Atayal one. Furthermore, the range of high DSNs was much greater than has been found before. Nine Ami and eleven Atayal subjects had DSNs between 23 and 25; two Atayal had DSNs of 26; one Ami had a DSN of 27; two Atayal had DSNs of 29; and one 11 year old Atayal boy had a DSN of 42. Seventeen of these twenty-six subjects described the taste at the DSN as other than bitter or qualified-bitter. Most of these values have special significance and will be discussed briefly later.

It should be pointed out that solution 42 contains only about $0{\cdot}6 \times 10^{-12}$ g PTC/l. and is about 4×10^{-15} M. If Moncrieff's[4] estimate that 0·05 ml. of solution (we use 2·5 ml.), properly applied, is sufficient for taste-testing is correct, the subject with a DSN of 42 must have been able to taste as little as 10^5 molecules of PTC. In this study, three of the subjects with scores of 25 and all with greater scores, except for one with a score of 26, were checked without their knowledge by adding a repeat series to the end of the test series. Only two of these subjects (one with a DSN of 26, and one with a DSN of 29) failed the repeat trial, and the boy with a DSN of 42 successfully completed two repeat trials.

Frequency distributions of taste acuity for PTC in human populations were earlier held to justify the

hypothesis[5,6] that three genotypes, TT, Tt and tt, are involved, but only two phenotypes, for the so-called "tasting" gene, T, was believed to be completely dominant over the "non-tasting" allele, t. Dominance, however, may be incomplete[7]. It has been contended more recently from consideration of data accumulated from thirteen samples each of 50, drawn mostly from separate ethnic groups, that the overall distribution calls for the recognition of at least five but more likely six modes[2,3]; and in a hypothesis (my work, unpublished) based on these data a case has been made for replacing the classical T, t gene-pair by an allelic series, T_1, T_2 – – – T_6, with possibly an additional allele, T_7, appearing in Japan. In terms of this hypothesis, I suggest that gene T_6 is present in both groups discussed in this communication but at greater frequency in the Atayal. Gene T_7 is present and at much the same frequency (of the order of 0·05) in both groups. There are indications that a gene, T_8, may be present, at least in the Atayal, and I feel there can be little doubt about the presence in this group of a further allele, T_x, though one may speculate at this stage about the value of x.

I thank Captain R. H. Watten, MC, USN, commanding officer, NAMRU-2, and Dr R. Q. Blackwell, head of the unit's department of biochemistry, for help and facilities.

Temporal Bounds of Post-ingestive Glucose Induced Satiety in Man

Most studies of the short term effects of the intake or administration of nutrients on hunger in man have been based on verbal reports. Whether these purport to describe the intensity of the desire for food—appetite itself—or the various sensations the subject habitually experiences when wanting food, the validity of such reports ultimately rests on what the subject wishes or does not wish to eat. We[1], in common with some other workers[2], have found it quite practicable to observe meaningful variations in the spontaneous size of meals taken when the subject is introduced to the experimental foods with little or no manipulation of his feeding behaviour before the experimental session. We wish to report here a study of the satiating effects which glucose produces after it has passed the mouth. It is intended to complement our previous study of the satiating effects of protein[1].

Twelve volunteers (one female) took their lunch and afternoon snack with us on 1 or 2 days per week when their mental and physical activities were not unusual. The primary foodstuff was a cooked cornflour and milk protein preparation, which was given as a savoury spread on crispbread and as a fruit-flavoured dessert (blancmange)[1]. A subject came at his usual lunchtime, was given a fixed amount of savoury and a hot drink and then allowed to eat as much dessert and drink as much water as he wished. He was counted as having finished when he stopped eating for at least 5 min, but he was kept for 30 min however soon he finished his lunch. The subject returned 3 h later to have as much dessert and water as he wished, staying for 15 min however soon he finished this supplementary snack. After the snack he was asked to describe that morning's breakfast and whether he had eaten a supper of unusual size or experienced any untoward reactions after any previous experimental day.

In the sessions reported here, the subject was given an additional 100 ml. drink at lunchtime. On some occasions this load contained 50 g of D-glucose, 0·5 ml. of 0·4 per cent quinine hydrochloride and 1 ml. of saturated citric acid solution. On other occasions a control load was given containing 2 ml. of 10 per cent (w/v) sodium saccharine, 2 ml. of saturated sodium cyclamate and 1 ml. of saturated citric acid. All solutions were at room temperature (21°–23° C). Subjects were instructed to gulp these drinks from the back of the throat; some did not even realize that the solutions were sweet. The drink was given either 20 min before or immediately before the beginning of lunch or immediately after finishing the meal according to our criterion. Sequences of conditions were counter-balanced between subjects.

Table 1. EFFECT OF GLUCOSE ON INTAKE PARAMETERS

Load	Timing relative to lunch	Food intake (kcalories) lunch	Food intake (kcalories) supplement	Water intake (ml.) lunch	Water intake (ml.) supplement	Duration (min.) lunch	Duration (min.) supplement
Glucose	20 min before	211*	131†	385	98	14·3	5·3
	Immed. before	295†	201	313	52	10·7	10·7
	Immed. after	331	158	309	100	19·2	9·5
Control	20 min before	322	177	305	80	15·8	8·4
	Immed. before	352	194	283	74	16·5	9·3
	Immed. after	335	201	295	58	15·3	12·0

Reliability of difference from relevant control condition, by correlated t test: * $P < 0·01$, † $P < 0·02$.

Table 1 shows the mean intakes for these six conditions. Glucose taken 20 min before lunch reliably depressed caloric intake relative to control load at both lunch and the supplementary snack (the depression of lunch calories relative to glucose after the meal was also reliable at $P < 0·01$). The intake of water at lunch was not increased reliably. Glucose taken just before lunch gave a detectable satiety at that meal, but half the size of that induced by the earlier load. Neither load given with lunch affected supplementary intake appreciably. The mean lengths of meals followed the pattern of variations in caloric intake but the differences between conditions were not statistically reliable.

The caloric content of the breakfast preceding a test was not found to differ reliably between conditions. On the occasions included in these data, no untoward reactions or unusually large or small suppers were reported. The caloric content of the experimental lunches were in the range 35–138 per cent of reported normal lunches (mean 87 per cent).

We conclude that there are gastrointestinal or post absorptive effects of glucose which induce a satiety from about 15 min after ingestion, which probably has largely disappeared less than 3 h later—which is 3–5 h before the next meal in these subjects. It seems therefore that the post-absorptive effects and gastrointestinal chemoreceptor and mechanoreceptor action of concentrated glucose solution of caloric value more than half the spontaneous intake do not act soon enough to account for the initial satiety which ends a meal in man. Reactions to the oral qualities of the foodstuffs available must constitute the principal factor in the first 20 min or so. It also seems that the glucogenic components of a meal are not dominant in maintaining satiety in the later phases of the inter-meal interval: we have already presented evidence that protein contributes more than carbohydrate or fat to keeping hunger at bay[1].

It should be noted that the post-ingestive satiety induced by glucose is not necessarily regulatory. Ingestion of glucose (188 kcalories) 20 min before the meal resulted in an approximately equicaloric reduction in total intake relative to saccharine ingestion at the same interval

before the meal (157 kcalories, Table 1). Glucose immediately before or after the meal, however, produced little net satiety (50 or 47 kcalories, respectively). Admittedly the supplementary sampling of satiety was limited to a brief period in mid-afternoon, but it is unlikely that 20 min difference in the timing of the load should shift compensatory reduction of intake so completely away from a period 3 h later. Rather, such a rapid completely behavioural caloric compensation may depend on the absorption of glucose load before the meal. In other circumstances it seems that either the behavioural regulation of body weight (or energy reserves[3]) takes more than a few hours or there is regulation by reduction of metabolic efficiency. Examples of lack of behavioural compensation even in the long term for energy-yielding loads have been seen in dogs[4] and rats[5].

We thank the staff and students who volunteered to participate in these experiments, which were supported by the Medical Research Council.

Lactose Synthesis by a Golgi Apparatus Fraction from Rat Mammary Gland

Lactose synthetase (UDP galactose : D-glucose 1-galactosyl transferase, EC 2.4.1.22) catalyses the final step in the synthesis of lactose of milk and is composed of two subunits, both of which are required for activity[1]. The A subunit is membrane bound and, in the absence of the B subunit, transfers galactose from UDP galactose to N-acetylglucosamine with the formation of N-acetyllactosamine[2–4]. The B subunit is identical to the milk protein α-lactalbumin, and modifies the acceptor specificity of the A subunit to include glucose[2,3]. Galactosyl transferase activities have been specifically localized in Golgi apparatus from rat[5] and bovine[6] livers. Because the localization of lactose synthetase activity has been the subject of much speculation[8], it was of interest to extend these studies to mammary tissue. We show here the A protein of lactose synthetase to be concentrated in a Golgi apparatus fraction from rat mammary gland.

Inguinal and thoracid mammary glands were recovered from first lactation Holtzman rats (Holtzman Co., Madison, Wisconsin) 2–6 weeks post-partum. Approximately 10 g of tissue was rinsed with ice-cold homogenization medium[5], minced and homogenized for 2 min in fresh medium using a Polytron '20 ST' homogenizer[5]. Cell fractions rich in Golgi apparatus, rough endoplasmic reticulum and plasma membrane as well as supernatant fractions were obtained from this homogenate as described previously[5,9–11]. Fractions were identified by electron microscopic examination of both negatively stained and sectioned material[9]. Lactose and N-acetyllactosamine synthetase activities were determined as described previously[5] by the method of Palmiter[4] in conditions of linear kinetics with respect to protein and time. Protein was estimated according to Lowry *et al.*[12] with bovine serum albumin as the standard.

Lactose synthetase, when assayed in the presence of exogenous α-lactalbumin, was concentrated in the Golgi apparatus fraction (Table 1). This activity was much lower or absent from fractions rich in plasma membrane and endoplasmic reticulum as well as from the microsomal supernatant. The reaction was dependent on added glucose and was stimulated by the addition of α-lactalbumin. The N-acetyllactosamine synthetase activity of the preparations was dependent on N-acetylglucosamine but was inhibited by α-lactalbumin as shown previously by Brew *et al.*[3]. Results in Table 1 are representative of mid-lactation animals. Although the lactose and N-acetyllactosamine synthetase activities were considerably lower for animals in the latter stages of lactation, the activity of the Golgi apparatus fraction was always approximately ten times that of the total homogenate.

When examined in the electron microscope, thin sections of pellets of the Golgi apparatus fractions showed fields containing stacks or dictyosomes comprised of parallel flattened cisternae surrounded by small vesicular profiles (Fig. 1). In negatively stained preparations, the Golgi apparatus were identified by the complex system of peripheral tubules (Fig. 2). These tubules correspond to the small vesicular profiles seen in thin section[9]. Rough endoplasmic reticulum and occasional mitochondria were the only contaminants detected in the Golgi apparatus fraction.

Except for the presence of more endoplasmic reticulum, the appearance of the Golgi apparatus fractions from mammary tissue was similar to those obtained from rat liver[9]. Measurements taken from a series of fifteen

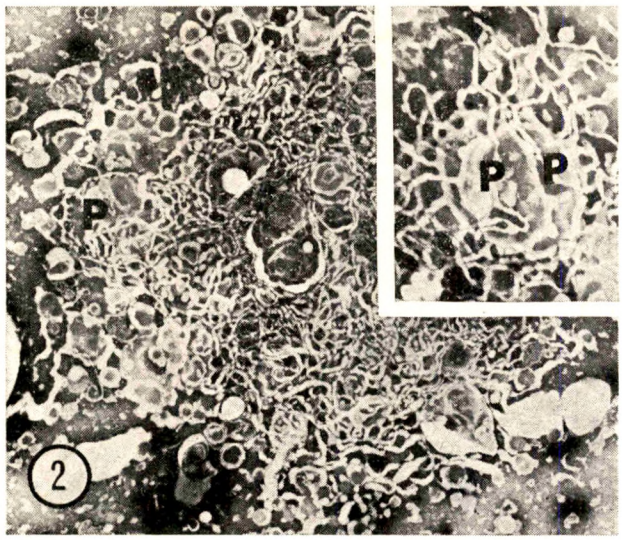

Fig. 2. A portion of the Golgi apparatus-rich fraction negatively stained with 1 per cent potassium phosphotungstate, *p*H 6·5. A complex array of plates (P) and tubules is revealed in the larger fragments which appear to represent aggregates of intact dictyosomes. ×16,000. Inset shows details of cisternal structure in a fragment of a dictyosome which was partially unstacked to show the system of peripheral tubules which are continuous with the plate-like central portions (P) of the cisternae. (×24,000.)

electron micrographs through a pellet centre suggested that 70–85 per cent of the pellet volume was Golgi apparatus, most of the remainder being rough endoplasmic reticulum. So the much higher specific activity of the Golgi apparatus fraction (Table 1) is a consequence of the presence of Golgi apparatus rather than a contaminating cell fraction although the true specific activity of Golgi apparatus membranes may be considerably higher than the present data indicate.

Table 1. LACTOSE AND N-ACETYLLACTOSAMINE SYNTHETASE ACTIVITY OF RAT MAMMARY CELL FRACTIONS

Fraction	Reaction mixture	Specific activity Lactose	Specific activity N-acetyl-lactosamine
Golgi apparatus	Complete	563·7	516·7
	−Acceptor	1·1	0·0
	−α-lactalbumin	34·8	1,457·0
Total homogenate	Complete	62·5	30·6
	−Acceptor	14·7	2·8
	−α-lactalbumin	21·7	123·7
Endoplasmic reticulum	Complete	6·2	76·1
	−Acceptor	2·6	0·0
	−α-lactalbumin	0·0	
Plasma membrane	Complete	0·0	
	−Acceptor	0·0	
	−α-lactalbumin	0·0	
Microsomal supernatant	Complete	19·4	
	−Acceptor	0·9	
	−α-lactalbumin	13·9	4·9

* The unit of specific activity is nmoles/h/mg protein.
For lactose synthetase the acceptor was glucose and for N-acetyllactosamine synthetase the acceptor was N acetylglucosamine. Assay conditions were identical to those used in a previous study[5] except that in this case complete reaction mixtures also contained 0·1 mg (6·5 nmoles) α-lactalbumin.

Our results confirm the suggestion of Brew[8] that the A protein of lactose synthetase is associated with the Golgi apparatus although we do not have evidence that it is exclusively localized there. Its occurrence in the Golgi apparatus has been suggested as a logical extension of the events known to occur during the secretion of milk constitutents[8,13]. During lactation, α-lactalbumin is synthesized on ribosomes and transferred to the lumen of the endoplasmic reticulum[14]. Secretory proteins are normally transported through endoplasmic reticulum to the Golgi apparatus where they are accumulated in secretory vesicles[15]. If a similar export route is assumed for α-lactalbumin, this would bring the α-lactalbumin into contact with the A protein of the Golgi apparatus membranes, creating the conditions necessary for lactose synthesis. It is therefore not unreasonable to assume that lactose may accumulate, along with proteins, in secretory vesicles of the Golgi apparatus and be d charged together into the gland lumen (see ref. 13).

Mounting Behaviour in the Female Cat

MOUNTING behaviour of the kind associated with t sexual activities of males has been observed in fema of a number of mammalian species, and has been exte sively investigated in the guinea-pig, rat and do Mounting by females has been observed in the cat, b it is said to be rare, and the conditions in which it occ have not been adequately defined[2]. This report provid data on the mounting behaviour of female cats kept social conditions in a laboratory, and on some of t factors determining its occurrence.

Observations were made on eleven multiparous fema cats, all over 16 months old, over a period of seve months. These cats lived as members of a larger gro of adult females and adolescents of both sexes, in indoor room 3 × 4·8 m, connected by way of cat-doo with an outdoor wire-fenced enclosure of the same si The outdoor enclosure had a common wire fence bounda with a similar enclosure which housed male cats. the observations were made in the outdoor enclosu with which the cats were thoroughly familiar.

The females were screened daily for signs of oestro behaviour, namely, crouching, flattening of the ba and hind-limb treading, sometimes accompanied vocalizations. The relationship of these behaviou signs to the ovarian and vaginal cycles is well esta lished[3]. The screening took place in the outdoor enclosu Sexually experienced males were present in the adjace enclosure separated from the females by a wire fence that social interaction between males and females w possible but mounting could not take place. In the conditions, any display of oestrous behaviour by the te females in the absence of physical contact with oth cats or with the observer was noted. Then, those fema not showing oestrous behaviour in the absence of conta stimulation were subjected to manual stimulation of t

rump and flanks by the observer, as a further test for the presence of lordosis. On the basis of this two-stage screening procedure, the females were selected for further observation on oestrous and anoestrous test days, defined as follows: (*a*) oestrous test day—oestrous behaviour in the absence of contact stimulation was observed for the third consecutive day; (*b*) anoestrous test day—all signs of oestrous behaviour, both in the absence of contact stimulation and in response to manual stimulation by the observer, were absent for the fourth consecutive day. Each female was given mounting tests on four oestrous test days, each from a different oestrous cycle, and four anoestrous test days. For these tests, the female was placed for 1 h with a group of fourteen cats, of whom three to five were oestrous females, six to eleven were females showing no signs of oestrous behaviour, and none to three were adolescent males and females between three and seven months old. If the required number of oestrous females was not naturally available in the colony, oestrogen-treated females showing the full pattern of oestrous behaviour were used. During the mounting tests, the performance of any components of male-like mounting behaviour by the test females was recorded, together with details of the age, sex and oestrous condition of the cat towards which the mounting behaviour was directed.

Ten of the eleven females in the group performed elements of the male mounting sequence. With the exception of the "chirp" call given by males before mounting, all the components which lead to intromission by the male were seen[4]—that is, neck-grip, partial mount, full mount, forelimb rubbing, hindlimb stepping, arching of the back, stamping on the mounted cat's rump (a pattern seen in males which increases the elevation of the female's perineal region during lordosis), and pelvic thrusting. Four of the females never progressed beyond the neckgrip and partial mount. Pelvic thrusting was seen in only three females, and had a lower frequency than is usual in males. There was considerable inter-individual variation in mean mount durations (3–414 s).

The orientation of the behaviour with respect to the mounted cat was sometimes bizarre, and in such cases the position of the "neck-grip" varied considerably. Mounting from the side and front was seen, as well as the normal posterior mounting. In mounts from behind, the mounting cat often had its pelvic region well forward on the back of the mounted cat, and occasionally during prolonged mounts the mounting cat would slide off and lie on its side, maintaining a neck-grip and continuing to clasp the mounted cat with its four paws. These poorly orientated mounts are reminiscent of descriptions of mounting by male cats in which the dorsal nerves of the penis have been sectioned[5].

There was a clear relationship between mounting behaviour and the oestrous condition of the mounting cat. The twenty-two test periods in which mounting occurred were all oestrous tests, and for the group as a whole there was a highly significant tendency for mounting to occur in oestrous rather than anoestrous tests ($P = 0{\cdot}002$, two-tailed sign test[6]). Furthermore, of the thirty-seven cats which were mounted, thirty-one were in natural or induced oestrus, five were females showing no sign of crouching or treading and one was an adolescent male. For the group as a whole, there was a highly significant tendency for mounting cats to choose to mount oestrous females ($P = 0{\cdot}001$, one-tailed sign test). The mounting female was an adequate stimulus to produce the full pattern of crouching, treading and tail-deflexion in the oestrous cat being mounted, but no after-reactions were observed, presumably because they are specific to vaginal stimulation resulting from intromission.

The predominant selection of oestrous females by the mounting cats may simply reflect the fact that other females will not tolerate being mounted, for it is known that the female cat will accept only a male at the height of oestrus[3]. Alternatively, stimuli from an oestrous cat may be specifically responsible for eliciting mounting by other females. During the tests, groups of oestrous females commonly consorted together, sniffing at each others' perineal regions, and engaging in mutual head and neck rubbing while treading. Pairs of oestrous females would roll on the ground, clasping each other, and would engage in prolonged bouts of mutual genital stimulation by crouching back-to-back, treading and rubbing their perineal regions together. Mounting episodes were frequently seen during these periods of head-rubbing and genital stimulation. Furthermore, a mounting female was frequently immediately mounted by the cat she was mounting, or by another oestrous female.

On the basis of these observations it appears that, in appropriate conditions, mounting behaviour forms a prominent part of the spectrum of social behaviour among female cats. It occurs at oestrus and is directed preferentially towards other oestrous cats. The conditions appropriate for the appearance of homosexual mounting behaviour in females have previously been investigated in detail in the guinea-pig, rat and dog. It seems that the cat may be somewhat more selective in its choice of objects to mount than are rats[7] and dogs[8], and, unlike these species but in common with the guinea-pig[9], it shows a tendency to restrict homosexual mounting behaviour to periods when circulating ovarian hormones are at a high level.

Lack of a Long-term Effect of LSD on Y-maze Learning in Mice

It has recently been reported that lysergic acid diethylamide-25 (LSD) has an inhibitory effect on T-maze learning in mice[1]. The animals were tested 2 min after an intraperitoneal injection of LSD, in view of the observations of Uyeno and Benson that the effect of LSD on agonistic behaviour approaches a maximum 5 min after injection[2]. Because of the controversy regarding potential long-term psychological effects of LSD, we had undertaken an examination of the effect on learning a shock avoidance task by repeated treatment of mice with increasing quantities of LSD over a long period. We report here the effect of this regimen on Y-maze learning in mice.

Twenty-four male mice of the NIH strain, 1 month old initially, and weighing 25 g, were given a series of sixteen subcutaneous injections of LSD (Sandoz batch 65001) at evenly spaced intervals over a period of 2 months. The first dose, administered when the mice were 30 days old, was 2·5 μg of LSD per mouse dissolved in 0·1 ml. of isotonic saline solution. The dosage was gradually increased to a maximum of 12·5 μg per injection, so that each mouse received a total of 111·25 μg of LSD. Twenty-four

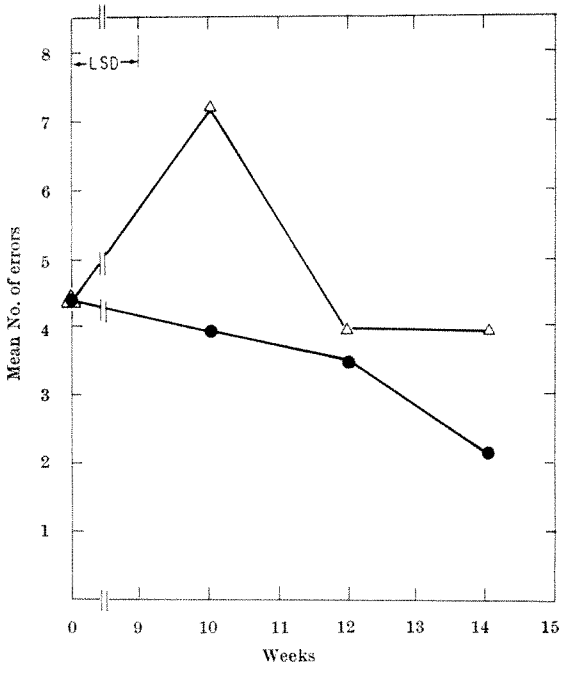

Fig. 1. Mean of errors in Y-maze learning of LSD-treated (△) and saline injected control (●) groups of mice.

age-matched controls were simultaneously injected with 0·1 ml. of saline solution. The mice were kept continuously from the beginning of the injection period in individual plastic cages and fed a standard commercial diet (Purina Lab Chow pellets) with water *ad libitum*. The mice which received LSD showed striking behavioural changes compared with the control animals. They were hyperactive for a period of several hours following each injection of the drug. They burrowed and tunnelled vigorously, climbed onto the spouts of the water bottle, ran inverted along the tops of the cages, and were found to be extremely aggressive in the presence of other mice.

Before administration of LSD, all forty-eight mice were tested for their ability to learn an avoidance task in the standard Y-shock apparatus described by Cardo[3]. This apparatus is a three-armed enclosure with hinged doors and a 1 cm × 1 cm wire grid over the wooden floor. The voltage applied to the grid is adjusted by a variable transformer and the operator can control the choice of exit arm by an electrical switching device, to eliminate the effect of possible bias on the part of the test animal. The mean number of errors at the time of original testing was $4{\cdot}3 \pm 0{\cdot}6$ s.e. (Fig. 1). The mice were then divided into two groups of equal learning ability and injected with LSD in saline or saline alone as described. The mice were re-tested 1 week after cessation of administration of LSD, by which time the signs of hyperactivity had disappeared. The mice which had received LSD showed an increase in the mean number of errors in the avoidance task to $7{\cdot}0 \pm 1{\cdot}03$ s.e., whereas the mean of the errors of the saline control group had decreased slightly to $3{\cdot}9 \pm 1{\cdot}09$ s.e. The difference between these groups is significant ($P = 0{\cdot}02$–$0{\cdot}05$) (ref. 4). The mice were tested 2 weeks later, when the mean number of errors of the LSD-treated group was $4{\cdot}0 \pm 0{\cdot}9$ s.e.—quite similar to that of $3{\cdot}5$–$0{\cdot}7$ s.e. for the control group. A subsequent test 5 weeks after discontinuing LSD injections indicated that the mean of the errors in the LSD-treated mice was still $4{\cdot}0 \pm 1{\cdot}1$ s.e. while that in the saline control group had decreased to $2{\cdot}2 \pm 0{\cdot}9$ s.e. This difference between the two groups is not statistically significant ($P = 0{\cdot}2$–$0{\cdot}3$).

The data obtained in the present experiment are consistent with the previous report[1] of an acute impairment of learning in mice as a result of administration of LSD. But the ability of the LSD-treated mice to learn an avoidance task had returned to the level of the control mice by 3 weeks after the chronic administration of LSD. We therefore conclude that there is no evidence of significant long-term impairment of learning attributable to LSD.

We thank Mr Donald Buttermore, head of the Department of Mathematics, Gunston, and Dr R. Brady, US National Institutes of Health, for their interest and for providing the LSD-treated mice.

Inhibitory Action of the Amygdala on the Lateral Hypothalamic Area in Rats

THE mammalian lateral hypothalamic area (LH) and the ventromedial hypothalamic nucleus (VMH) are involved in feeding and satiety function, respectively[1]. There is also reciprocity of electrical activity between the two[2]. Anatomically related to these areas, the amygdala has been shown to be involved in the same functions. Lesions of the basolateral nucleus of the amygdala results in hyperphagia[3], while its electrical stimulation arrests feeding behaviour[4]. The stimulation of the amygdala also produces changes in the spontaneous discharge pattern of LH units, suggesting an inhibition or an activation–inhibition sequence between the LH and the amygdala[5,6]. We report here evidence that the inhibitory effect of the amygdala on the LH neurone is due to a long lasting inhibitory postsynaptic potential (IPSP) exerted through the stria terminalis.

While rats were under light ether anaesthesia[6], intra and extracellular potential recordings were made from neurones in the centre of the LH[6] by means of glass microelectrodes filled with 3 moles of KCl (d.c. resistance, 20–80 MΩ). While intracellular recordings were being made, polarizing currents were applied across the cell membrane through the recording electrode by means of a modified constant current device[7]. Bipolar stimulating electrodes (40–80 kΩ) were always placed in the amygdala[6] and in the stria terminalis (A, 4·38; L, 3·50; H, +7·70, after König and Klippel[8]). Stimulating pulses lasted 0·1 ms and were less than 0·2 mA in intensity.

Single pulse stimulation to the amygdala produced a characteristic evoked potential in the LH consisting of an initial negative deflexion followed by a positive deflexion (N and P waves respectively, upper left of Fig. 1*A*). Mean latency and peak time of the N wave were about 6 and 12 ms respectively. The P wave lasted about 30 ms, and the N wave always appeared at a lower threshold than the P wave. Furthermore, the depth profile of the N and P waves within the LH differed in distribution—P waves were recorded almost equally throughout the dorso-ventral extent but N waves mostly in the ventral half. Thus each wave seems to be mediated by a separate pathway.

The evoked potentials produced by paired stimuli to the amygdala (Fig. 1*A*) showed the inhibitory nature of the P wave on the N wave. As the interstimulus interval was decreased, the amplitude of the N wave to the second stimulus became progressively suppressed, as

shown by the plot (Fig. 1*B*) of the amplitude of the N wave as a decreasing function of interstimulus interval from 90 to 10 ms. The P wave, on the other hand, remained virtually unchanged. Thus the inhibition caused by the P wave might be due not to its recurrent nature, but to its postsynaptic or presynaptic nature. The latter could be excluded after the depth profile of the P wave had been considered in comparison with the P wave produced by presynaptic inhibition[9]. On single unit recordings, the LH neurones responded with one to two driven spikes about 10 ms after stimulation of the amygdala (Fig. 1*C* and *D*). The latency corresponded to the peak time of the N wave. This was followed by a long lasting suppression of spontaneous firing for up to about 100 ms (Fig. 1*C*). Driven discharges, which would be produced by the second stimulation at various times after the first stimulation, were also inhibited for about 100 ms (Fig. 1*D*), although the latency of the first driven discharge was shortened at the stimulus interval by about 2 ms (second recording from the top in Fig. 1*D*). This was probably a summation of the N wave (to be discussed later). The time course of the suppression of the unit discharges corresponded to that of the N wave.

These findings suggest that the N and P waves reflect excitatory and inhibitory postsynaptic potentials respectively. We have proved this to be correct. First, temporal summation of the first two N waves was observed as a result of repetitive stimulation of the amygdala at 300 Hz; then the third N wave was decreased by the following P wave. The summation of P waves to the first three pulses of 150 Hz was also observed. Second, the post-tetanic potentiation was observed, for example, an increase in the amplitude of the N wave 1·8 times after 1·3 s of a tetanic stimulation (threshold intensity for N wave, 30 Hz for 6 s); the P wave could also be potentiated 1·5 times after 1·3 s (1·5 times threshold, 25 Hz for 2·5 s).

The hypothalamus, including the LH and VMH, receives fibres from two anatomically distinct pathways of the amygdala: the stria terminalis and the direct amygdalohypothalamic tract (DAH)[10]. An acute lesion of the VMH, regarding the reciprocal activity between it and the LH, made by passing a strong d.c. current (5 mA for 30 s), produced no change in the response of the LH, but that of the stria terminalis resulted in the disappearance of the P wave and the prolongation of the N wave. These results may indicate that the N wave was elicited through the DAH, and the P wave through the stria terminalis.

Intracellular recordings, which were consistent with this interpretation, revealed a similar excitatory–inhibitory sequence of potentials; that is, an excitatory postsynaptic potential (EPSP) followed by an IPSP. Although the IPSP lasted about 100 ms while the duration of the P wave was 30 ms, the difference can be attributed to differences in intracellular potential and extracellular current fields[11].

Intracellular recordings are shown in the upper trace of each record in Fig. 2*A*. The EPSP and IPSP lasted about 15 and 100 ms respectively. Each lower trace is an extracellular record made soon after the withdrawal of the electrode from the cell, and the initial positive

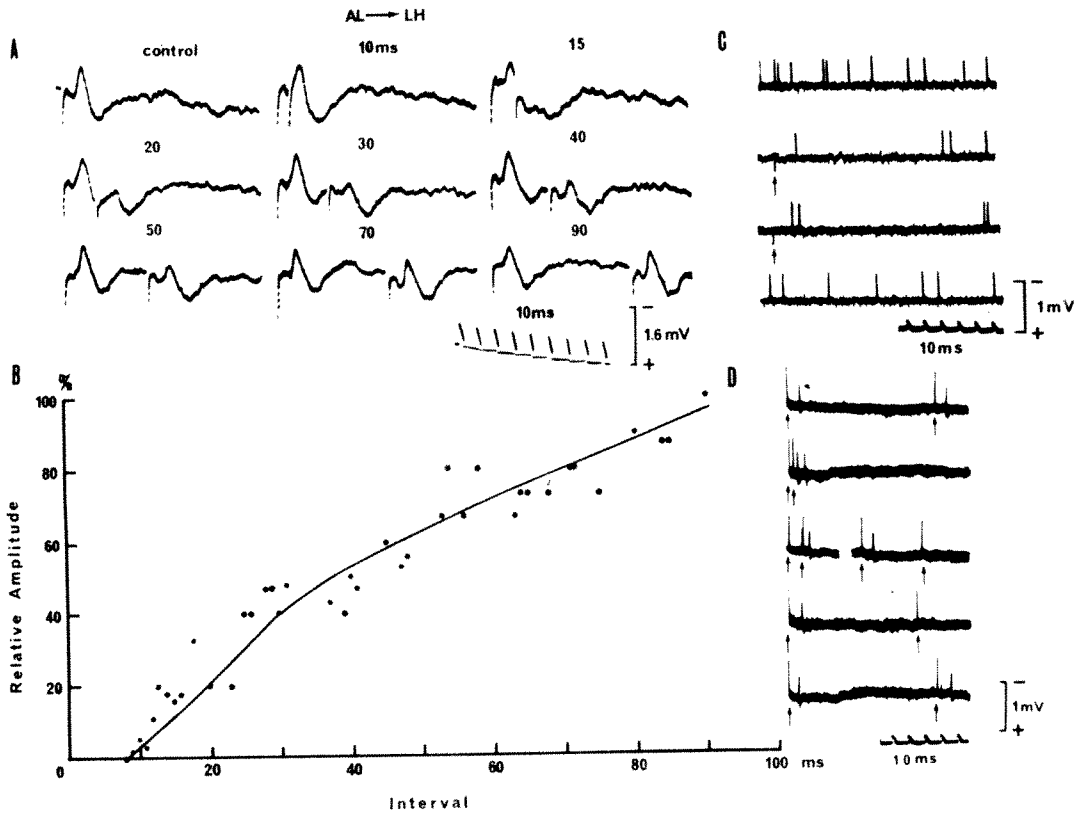

Fig. 1. Extra-cellular records from LH neurones in response to single stimulations of the amygdala. *A*, Time course of inhibition of the N waves during a conditioning P wave. The top record on the left shows the control N and P wave sequence produced by a single stimulation pulse. Test stimulations were applied at various intervals, indicated by values (in ms) above each record. Stimulus intensity was more than twice that of the threshold. *B*, Sizes of test N waves are plotted against conditioning-test intervals as percentages of the control. Each point is the mean value of result of ten trials. Note the inhibition of the N wave lasting about 100 ms in comparison with the time course of the P wave lasting about 30 ms. *C*, The uppermost record shows spontaneous unit discharges of a LH neurone; in the second and third records, driven unit discharges (one or two spikes) with 10–20 ms latency are followed by an inhibition of spontaneous unit discharges lasting about 100 ms; the lowermost record shows the spontaneous discharges 1·25 s after the third record. *D*, Similar experiments to those in *B*, but involving unit discharges. Test stimulations of the amygdala were applied at various intervals. One driven unit discharge appeared at the latency of about 10 ms. Arrows indicate stimulus artefacts. The top and bottom records served as control. The latency became shortened when the stimulus interval was about 2 ms (second record from top). In the third record (left), the driven discharge overlapped on the stimulus artefact. The test stimulation could not produce the driven discharge at intervals of up to about 100 ms.

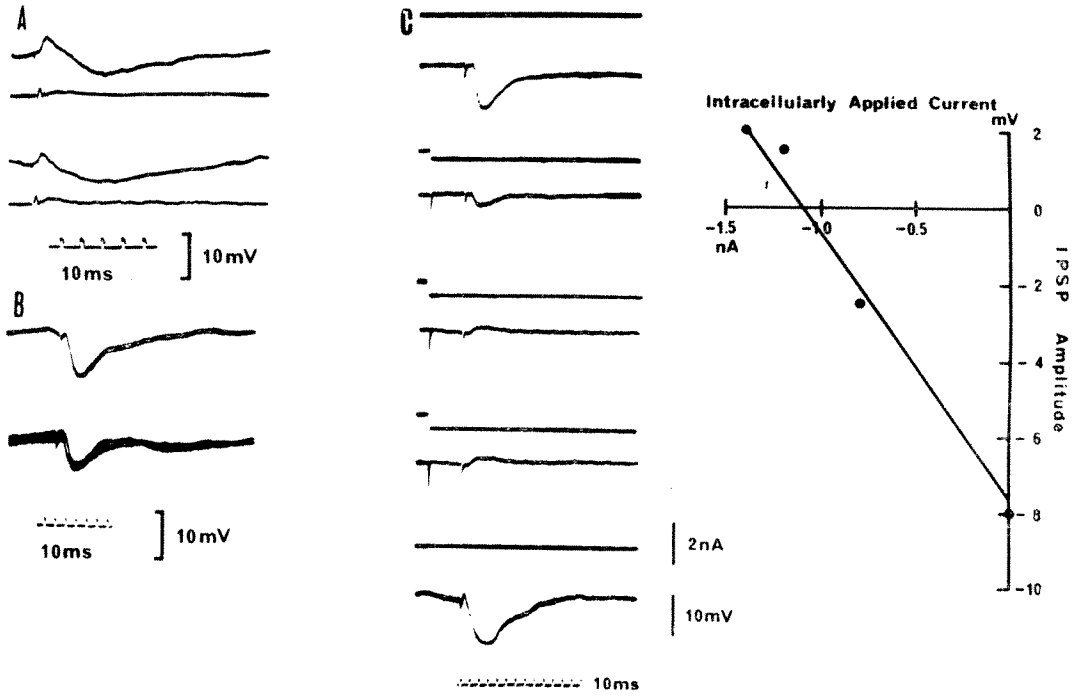

Fig. 2. *A*, Intracellular recordings of synaptic potentials in two LH neurones in response to stimulation of the amygdala. The upper trace in each pair is EPSP followed by a long-lasting IPSP being about 100 ms. The lower trace is an extracellular recording elicited by the same stimulus intensity, immediately after withdrawal of the electrode from the same cell. The small brief positive spike just after the stimulus artefact may represent the action potential from the presynaptic terminals. *B*, Shows the intracellular IPSP in two LH neurones. The upper record is a single trace of IPSP without association of preceding EPSP; the lower records, four traces were superimposed. Note the delayed IPSP with smaller amplitude. The resting potential of these neurones was about −50 mV in *A* and *B*. *C*, Reversal in the polarity of IPSPs recorded intracellularly in a LH neurone. Inward currents were applied through the same recording electrode filled with 3 M KCl. On the left, the upper traces of each record indicate the intensity of the inward current. The top and bottom recordings were obtained 1·25 s before and after the application of current. Right, relationship between the intensity of the inward current and the amplitude of IPSPs. Reversal point is at 1·1 nA. The resting potential was −50 mV.

deflexion may represent presynaptic activity. Other examples showed only IPSPs without the preceding EPSP (Fig. 2*B*). The IPSP was readily reversed in polarity when inward current was applied intracellularly (Fig. 2*C*, left). On the right of Fig. 2*C* the amplitudes of the IPSPs are plotted against the injected current. The inward current at the reversal point of the IPSP was $1{\cdot}1 \times 10^{-9}$ A.

This powerful action of the postsynaptic inhibition may account for the effective suppression of the feeding behaviour and also of the spontaneous activity of the LH neurone.

Alpha Rhythm and Fine Eye and Eyelid Movement

The source of the alpha rhythm of the EEG was originally attributed to activity within the central nervous system, and, in particular, suppression of the rhythm to processes of vision[1,2], attention[3], or cognition[4,5]. But failure to relate the waveform measured at the scalp to the behaviour of cortical neurones has recently provoked discussion of an alternative generator[6,7]. Lippold has proposed that the alpha rhythm represents a modulation of the corneo-retinal potential caused by ocular tremor[8,9]. In order to test this hypothesis we have investigated the correlation between ocular tremor and alpha activity, as suggested by Good[10].

The subjects were healthy males aged 18–45, in whom the alpha rhythm had been found in earlier experiments to persist while the eyes were open (p-types)[11]. EEG recordings were made from positions C_3–A_1, C_4–A_2, O_1–O_2 P_z–A_2 (ref. 12) using a Beckman dynograph. Simultaneous recordings of eye movement were obtained by the following photoelectric method, modified from Stark and Sandberg[13]. Subjects wore a pair of spectacle frames to which were attached a source of red light and a single phototransistor. The latter monitored light reflected from the lower temporal quadrants of the right eye. Because the average brightness of this region changes as the margin of the iris moves, the output of the phototransistor provides an index of ocular activity. This output was calibrated with respect

to vertical and horizontal movements, though sensitivity is not linear for all vectors of movement. Recordings were made while subjects, seated in a darkened and sound isolated chamber, fixated a dimly illuminated point source.

Simultaneous recordings of EEG and eye movement are seen in Fig. 1. It is clear that bursts of alpha activity can and do occur without detectable eye tremor at these frequencies (Fig. 1*a*). At other times slower high amplitude ocular movements appear to be "notched" at alpha frequency while the EEG shows only characteristic alpha activity at about 10 Hz (Fig. 1*b*).

The photoelectric sensor responded also to movement of the eyelid when the eyes were closed. Fig. 1*c* shows that fairly long periods of correspondence occurred between eyelid flutter and alpha rhythm of the EEG. In these conditions eyelid movement may reflect activity of the levator palpebrae or passive movement from ocular tremor. If the latter is the case, then ocular tremor at alpha frequency must have increased in amplitude relative to other frequencies while the eyes were closed. This is not accompanied by any increase in the amplitude of the alpha rhythm of the EEG. Alternatively, the sensor may record merely the characteristic tremor of skeletal muscle; in this case, of the levator palpebrae.

Saccades of less than 2° occurred without appearing to contaminate the EEG and, in fact, ocular tremors of 10° or more would be necessary to produce an artefact of alpha rhythm in the manner suggested by Lippold. Such tremors were not observed.

Where ocular tremor contained activity at alpha-like frequency, five second samples of the simultaneous recordings were subjected to time series analysis on a Noratom ISAC computer[14]. Alpha rhythm was present in the EEG record for all samples. Fig. 2 shows that its peak occurred at approximately 10 Hz both when the eyes were open or closed. By contrast, the eye sensor channel shows a peak at 5 Hz. This was prolonged as a plateau to 10 Hz when the eyes were closed, representing the faster component of eyelid flutter (Fig. 2*c*). It is notable that even in these records, selected for maximum content of alpha frequency in the eye movement record, 10 Hz is not the predominant frequency. If ocular tremor generated the alpha rhythm the peak frequencies should be the same in both records.

The autocorrelations in Fig. 3 indicate largely random eye movement and eyelid flutter, whereas all three EEG traces show a pronounced rhythmicity at 10 Hz. In the first records, Fig. 3*a*, there is no indication of 10 Hz

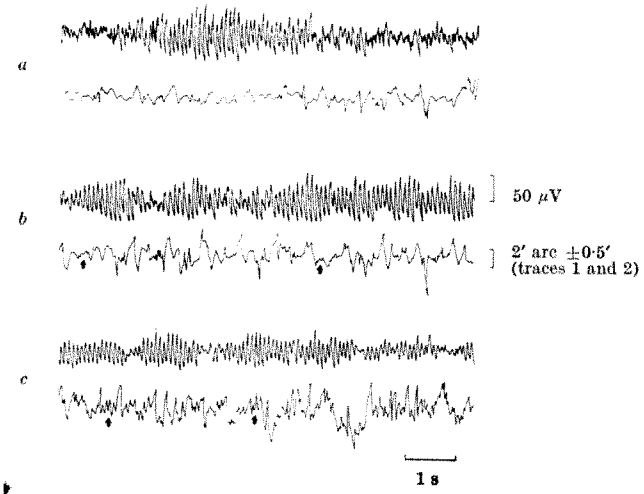

Fig. 1. Simultaneous records of EEG (P_z–A_2) (upper trace of each pair) and eye movement (lower trace). *a*, Recording made with eyes open. Note the large burst of alpha activity unaccompanied by corresponding 10 Hz activity in the sensor trace. *b*, Recording made with eyes open; arrows indicate periods when eye movement appears to be notched at alpha frequency. *c*, Recording made with eyes closed. Sensor reveals eyelid flutter. Signs of activity at alpha frequency in eyelid flutter are even more pronounced.

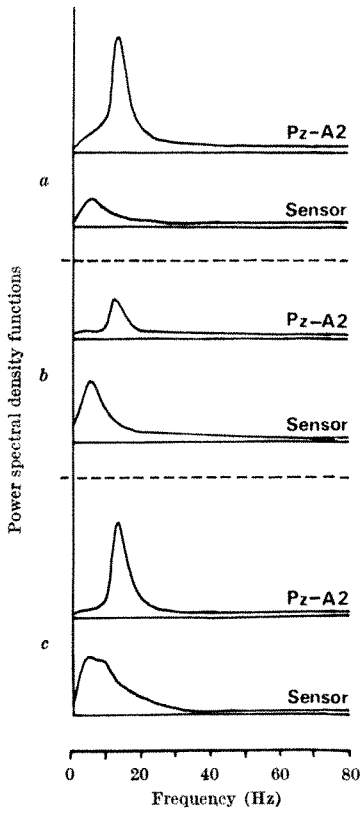

Fig. 2. Power spectral density of EEG and eye movement/eyelid flutter obtained during periods of high alpha-like activity in the sensor channel. *a* and *b*, Eyes open; *c*, eyes closed.

rhythmicity in the autocorrelation of the eye movement, and cross correlation with the EEG fails to reveal any relation between them. In the second record, Fig. 3*b*, there is again no evidence of rhythmicity at 10 Hz in the eye movement but cross correlation reveals a common component. This stands up to the test of normalization by calculation of the cross products of the standard deviations of the two autocorrelations. After normalization, however, common 10 Hz activity is greater between eyelid flutter and the EEG (Fig. 3*c*) than between ocular tremor and the EEG (Figs. 3*a* and *b*). This result might have emerged if the 10 Hz component of the EEG had been stronger when the eyes were closed. But of the samples selected, alpha activity was most powerful in the first record taken while the eyes were open (Fig. 3*a*) and no cross correlation was evident.

These findings are inconsistent in a number of respects with the view of ocular tremor as a generator of alpha rhythm. The predominant frequencies of ocular tremor are markedly different from those of simultaneously recorded alpha rhythm. The random components of ocular movement contrast with the redundancy of the alpha rhythm; one would expect coherent signals originating in the orbit to be obscured by superimposition of neuronal activity when measured at the scalp. In fact, the reverse is observed. Even if, in the present study, the eyeball were oscillating at alpha frequency under the closed lid, such movement is evidently not essential for the appearance of alpha rhythm at the scalp. In view of the relationship between the amplitude of saccades and the artefacts[15,16] they induce in the EEG, one would expect to record very conspicuous tremor of the eyeball when alpha rhythm occurred with the eyes open. This was not the case.

Although these findings seem to preclude an orbital origin for the alpha rhythm, the cross correlations of Figs. 3*b* and *c* argue for a weak interaction in the opposite direction. That is to say, eye movement may be modulated by alpha rhythm. This will occur when conscious control of fixation wanes or is interrupted by eye closure. In

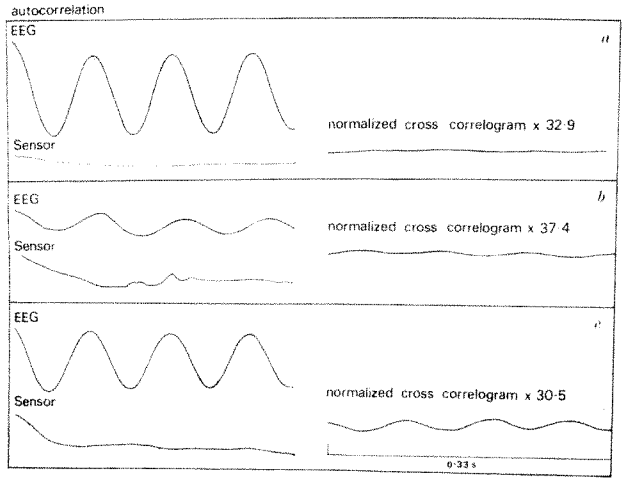

Fig. 3. Auto and cross correlograms of EEG and eye movement. In each group of traces, the upper left trace shows the autocorrelogram of the EEG; lower left: autocorrelation of the eye movement/eyelid flutter; right hand trace: cross correlogram of EEG and eye movement/eyelid flutter. *a* and *b*, Eyes open; *c*, eyes closed. The numeric factors (obtained from the cross product of the standard deviations of the autocorrelation functions) necessary to normalize each cross correlation are indicated above the respective cross correlograms. The phase difference between cross correlograms *b* and *c* has no biological significance.

these conditions the oculomotor, abducens and trochlear nuclei are deprived of information for the servo control of fixation and may become more susceptible to extraneuronal current flow at alpha frequencies. The greater correlation between eyelid flutter and EEG may reflect a similar process operating on that part of the oculomotor nucleus not directly involved in fixation.

We thank Mr A. W. Kwiatkowski and Mr J. C. Shaw for discussion of problems of time series analysis. The work was supported by the Endowment Research Fund of the United Birmingham Hospitals.

Paired Comparison Technique for measuring Stimulus Control Functions in the Pigeon after Training with Discrete Trials

Since the work of Skinner and his associates[1], free responding techniques, in which an organism can respond repetitively without altering the stimulus situation, have commonly been used in studying discrimination learning in the pigeon. Guttman and Kalish[2] developed a procedure for obtaining reliable measures of response strength at different "values" along a "stimulus dimension" (for example, wavelength of a patch of light); from these, "stimulus control functions" could be plotted. This procedure has been used by Hanson[3] to obtain post-discrimination stimulus control functions, and later workers have used a wide variety of experimental designs and stimulus dimensions[4]. In a free responding situation however, as Jenkins has pointed out[5], the assessment of stimulus control may be subject to error from confounding effects—for example, a reinforcement within a stimulus presentation may in itself lead to an increased rate of responding on that presentation. He suggests that these effects can be overcome most easily by the use of a discrete trial training procedure, in which the organism's response terminates the trial. But the free responding Guttman and Kalish procedure for measuring stimulus control functions then becomes inappropriate.

This testing procedure has been developed after unsuccessful attempts to measure stimulus control functions in a discrete trial situation using various dependent variables, for example, latency of response, number of responses to extinction. It involves a paired comparison test in which a test trial consists of the presentation of two stimuli occupying different values on the stimulus dimension tested. A single response by the pigeon to one of these two stimuli terminates the trial and over successive test trials all possible combinations of pairs of stimuli from a given set of test stimulus values are presented, as in conventional uses of the paired comparison technique. Stimulus control functions are then obtained with number of choices of test stimulus values as dependent variable. David[6] has developed a range of statistical tests for use with paired comparison data in this form. It is also possible to obtain scale values in terms of one or more of the theoretical models developed for paired comparisons and to assess the goodness of fit of data to model[7].

As the test involves a choice between two stimuli there are complexities in interpretation in intra-dimensional designs (that is, in designs where both training stimuli have values along the test stimulus dimension) in that the bird's response may be based on the relationship between the two stimuli, rather than the absolute value of the reinforced stimulus. Thus the test is most suitable for use in interdimensional designs (designs where only one training stimulus has a value on the test stimulus dimension) and in extradimensional designs (designs where neither training stimuli have values along the test stimulus dimension), where such relational explanations are not possible.

In order to produce a high resistance to extinction so that a large number of test trials can be used in the absence of reinforcement, pigeons are given extensive training at a low probability of reinforcement for pecks at the positive training stimulus, S^+ (typically 0·125 or 0·1). In this way reliable stimulus control functions have been obtained after single stimulus training, successive go/no-go and simultaneous discrimination training.

As an example of theoretical interest, results obtained from a simultaneous discrimination using an interdimensional design are cited. Four experimentally naive 2–3 year old cock pigeons were maintained at 80 per cent of their free-feeding weight. They were trained in a sound attenuated chamber on one wall of which were two 1 inch diameter response keys with 1·5 inch between their centres and at the same height. In training a trial started when both keys were trans-illuminated, one key showing S^+ (a red circular disk), the other showing S^- (a grey line at 45° to the horizontal, with red circular surround—the red and grey parts being equated for brightness by a human observer). A single peck at S^+ darkened both keys, gave access to 4 s reinforcement of mixed grain and initiated an inter-trial interval of 10 s. A single peck at S^- darkened

both keys and initiated the inter-trial interval. Any inter-trial responding delayed the onset of the next trial until 10 s after the last peck. Such inter-trial responding was rare. S^+ appeared with equal frequency on left and right keys, as determined by Fellows[8] sequences. Stimulus presentation and reinforcement contingencies were controlled automatically by conventional electromechanical devices in a separate room from that containing the training chamber. Pigeons were run in daily sessions of forty-eight reinforcements until at least 90 per cent correct responding occurred on three successive sessions. The probability of reinforcement for pecking at S^+ was then dropped successively to 0·5 (two sessions of forty-eight reinforcements), 0·25 (two sessions of forty-eight reinforcements) and finally 0·125 (ten sessions of twenty-four reinforcements each). A correction procedure was used throughout such that a peck at S^- on a trial when reinforcement was available on S^+ led to S^+ only being presented, in the same position, on the next trial. Pigeons were then tested on three successive sessions. A total of sixty test trials were run per session.

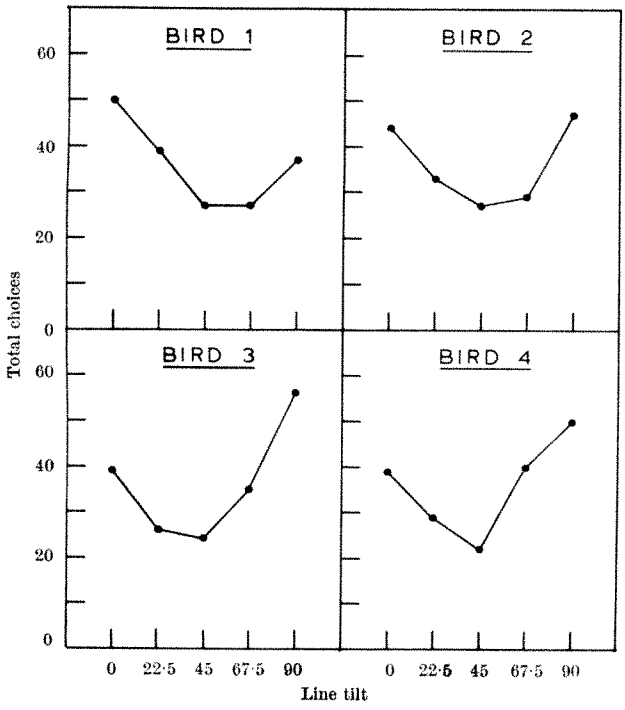

Fig. 1. Total number of choices of different line tilts during paired comparison testing after training on a simultaneous discrimination with S^+ a red disk and S^- a grey line tilted 45° clockwise from the vertical, with red surround. All pigeons show the U-shaped function with minimum at the trained S^- tilt, indicating stimulus control by S^-.

Pairs of stimuli taken from a set of five having grey lines tilted at 0°, 22·5°, 45°, 67·5°, and 90° to the vertical, each with red surround, were presented. Each block of twenty trials contained all possible combinations of test stimuli presented in randomized sequence. All test trials were run in extinction, all birds responding on all test trials. Test trials were preceded by five reinforcements at a probability of reinforcement of 0·125 for response to S^+ and followed by nineteen reinforcements in the same condition.

Fig. 1 shows the results of these tests. Statistical analysis[6] shows differences between the overall totals of choices of different line tilts for individual birds at $P < 0{\cdot}01$ for all pigeons. The U-shaped stimulus control functions indicate that S^- has attained control over responding. Thus the assertion made by Bloomfield[9] that simultaneous discriminations are explicable purely in terms of the rule: go to S^+, is incorrect. It has frequently been suggested[10–12] that the peak shift effect[3] occurs if, and only if, S^- has developed stimulus control. As peak shift has not been found in the simultaneous discrimination situation (ref. 13 and unpublished results of R. L. Rudolph), this finding of control by S^- in a simultaneous discrimination casts doubt on the generality of this suggestion.

GENERAL

Occupational Orientations at Bradford and Warwick Universities

IT is well established that occupational attitudes can be shaped by educational experiences[1], but comparatively little is known about the specific effects of a British university education. Becker *et al.*[2,3] have differentiated the effects of higher vocational and non-vocational education in the United States. They found attitude changes to occur, but whereas, in the former, students came to see themselves as members of their prospective professions, in the latter, they tended to identify with their subjects. Various official reports[4,5] in recent years have taken the view that university education in Britain chiefly promotes identification of the second kind.

These reports are expressions of a climate of opinion which has greatly influenced the development of university education in recent years. For example, the technological universities have been established with the aim of providing an education related to industrial needs.

Studies among scientists[6,7] have shown that they can be characterized in terms of the relative importance they attach to professional goals (for example, advancing knowledge by fundamental research) and organizational goals (for example, producing results useful to employers). The two orientations are not, of course, mutually exclusive, but most scientists probably emphasize one set of goals or the other. How this bias develops is little understood, but the view of the Jones and Swann Committees[4,5] seems to be that pure science courses influence students in the direction of professional goals. Given the distinctive aims of applied science courses, they might be expected to produce an organizational emphasis.

Goldberg, Baker and Rubenstein[8] have devised scales for assessing the relative strengths of professional and organizational orientations, and these have recently been refined and modified for use among British students by Child and Musgrove[9]. The questionnaire asks subjects what weight they would give to a number of factors in judging the worthwhileness of a project.

At the University of Bradford, in 1967, a longitudinal study was started among science and engineering students entering the university for the first time in an attempt to shed some light on the assumption of occupational identities. Among the questionnaires administered was the Child–Musgrove questionnaire. The same students were approached again in January 1970, when they were in the third year of their four year courses. The initial response rate was good—86 per cent—but in the follow-up study only 41 per cent of those who had reached the third year returned usable questionnaires. Engineering students who responded on this second occasion were somewhat more organizational on entry than non-respondents (means: respondents 25·3, non-respondents 23·9, $t=2·07$, $P<0·05$), but otherwise the 1970 respondents were representative of the sample as a whole.

At the University of Warwick a longitudinal study of the development of occupational attitudes was started in January 1969, among students who were in their first year. Like the Bradford study, this survey included the Child–Musgrove questionnaire and, to provide some comparative data, it was also given to a sample of third year students. Percentage returns were consistent among the various groups giving an overall figure of 64 per cent.

Data from the Bradford and Warwick studies are presented in Table 1. The group of applied scientists at Bradford comprises students from the Schools of Applied Physics and Industrial Chemistry; the group of pure scientists at Warwick comprises students from the science faculty reading the nearest equivalents to the Bradford disciplines. The sample of engineering students at Bradford includes students from three schools—chemical, electrical and mechanical engineering—and these are compared with students at Warwick reading engineering science.

Table 1. PROFESSIONAL AND ORGANIZATIONAL ORIENTATIONS OF FIRST AND THIRD YEAR STUDENTS AT BRADFORD AND WARWICK

University and field of study	Professional scores 1 N	Mean	s.d.	3 N	Mean	s.d.	Organizational scores 1 Mean	s.d.	3 Mean	s.d.
Bradford										
Applied science	44	21·3	4·5	14	20·2	4·2	23·1	4·4	19·8	5·1
Engineering	191	20·3	3·6	42	20·5	3·6	24·2	3·1	23·0	4·1
Warwick										
Pure science	58	22·0	3·8	51	20·3	4·0	20·1	5·1	19·5	5·4
Engineering	40	20·5	3·7	19	19·8	4·4	22·4	3·7	22·8	3·6

The data of Table 1 show that the two universities seem to be attracting students with different occupational orientations. Both the Bradford engineers ($t_1=2·34$, $P<0·02$) and the Bradford applied scientists ($t_1=3·18$, $P<0·01$) were significantly more organizational on entry than their Warwick counterparts. (t_1 = significance of difference between independent means). First year science students at Warwick were significantly more professional than organizational ($t_2=2·42$, $P<0·02$). (t_2 = significance of difference between correlated means.) But on entry the Bradford applied scientists ($t_2=1·63$, $P<0·15$) like the engineers at both Bradford ($t_2=7·12$, $P<0·001$) and Warwick ($t_2=2·09$, $P<0·05$) tended to be more organizational than professional.

Comparing first and third year data, few changes seem to have occurred among the engineering students. Their professional scores remained constant at both universities, and Warwick third year students were as organizational as those in the first year. Bradford engineering students, however, became less organizational over two years ($t_2=4·11$, $P<0·001$) so that among third year students organizational orientations in the two universities were similar.

The professional scores and organizational scores of scientists in the two universities also converged. The Bradford applied scientists, who were the more organizational at the outset, became significantly less organizational over two years ($t_2=2·55$, $P<0·05$). Conversely, at Warwick, third year pure science students were significantly less professional than first years ($t_1=2·27$, $P<0·05$).

These results contain elements which were anticipated, but also elements which are altogether surprising. Research in the United States has indicated that different universities characteristically attract different student populations. Astin[10], for example, found that student choice and institutional selection resulted in the enrolment of students whose "educational and vocational plans are remarkably suited to the curricula offerings of the institutions". In our study, the organizational emphasis of students entering the University of Bradford matches the publicized aims of the technological universities.

American research has also revealed the different occupational orientations of both student[11] and practising[12] scientists and engineers and these also appear in our study.

But what was wholly unanticipated was the convergence of the occupational orientations of applied scientists at Bradford and pure scientists at Warwick. In spite of the different intentions of the courses, it seems that their outcomes in this respect were similar. This raises two important considerations.

First, the contention of the Jones and Swann report does not appear to hold. The study of the pure sciences at university does not seem to cause students to espouse professional and eschew organizational goals, at least when the whole attainment range is considered. Gannicott and Blaug[13] have recently reached a similar conclusion from a quite different line of evidence.

A second doubt concerns the distinctive contribution of courses like applied physics and industrial chemistry. This has been challenged before, by Wyatt[14], for example, who showed that some applied science courses differed little from their pure equivalents apart from the compulsory periods of industrial training. While this is probably not generally true, and there may be considerable differences in content, the pure sciences and their applied variants are alike in being specified by the empirical phenomena studied. In this they differ from engineering and other technologies which are organizations of knowledge around practical problems[15]. The pattern of occupational orientations reported here suggests that the pure and applied sciences may lie within the same, and engineering within a different, "boundary of influence"[16].

We thank Professor F. Musgrove, who is in overall charge of this work, for advice.

Book Reviews

WHERE ECCLES ERRED

Policy and Practice

The Colleges of Advanced Technology. By Tyrrell Burgess and John Pratt. (LSE Studies on Education.) Pp. xvi+236. (Allen Lane, The Penguin Press: London, November 1970.) 105*s*.

THE expansion of higher education in Great Britain from the mid-1950s on is associated above all with the enthusiasm and dynamic energy of one remarkable man, now Lord Eccles, who was Minister of Education for two periods during a critical time, and his team of devoted civil servants. The expansion was based on three points of view, all of which turned out to be incorrect. The first was that the rise in the number of students to be expected largely arose from the increase in the size of the age-groups entering higher education, chiefly as a result of the post-war birth boom. In fact, it related to an increase in the proportion of the age-group staying on at school. Even in the Robbins report there was a considerable underestimate of the likely numbers who would be coming forward. Provision for higher education expansion, relatively lavish though it may have seemed, has therefore always been too little and too late. In this respect the British experience, it must be admitted, is no different from that elsewhere.

Second, it was assumed that the major sector of the expansion, other than that in teacher training, should be in places for science and technology. This ran counter to the student demand, with the consequence that not only do some science and technology departments stand relatively empty in parts of the country, but also the qualifications for admission to those courses have been significantly lower than the qualifications for admission on the arts and social sciences sides. Even today the universities, with 55 per cent of their existing provision for science and technology, are planning to make 55 per cent of their new provision in the quinquennium 1972–77 in the same field. It is likely that some of these expanded departments, especially in physics and chemistry, will become museums to the history of ideas rather than places where students are actually taught.

Third, it was assumed without argument that the expansion in the supply of trained scientists and technologists would automatically lead to economic growth and, indeed, would be required by it. In the event, there is little evidence and less systematic argument to connect the growth of the economy with the development of science and technology. Indeed, it is almost certain that the growth of research in science, in particular, is a consequence rather than a cause of the growth of the national income. So powerful, however, is the desired association of ideas, the faith that the rate of growth of the national income depends on the expansion of industry, and the expansion of industry on the recruitment of engineers, and the training of engineers on the development of the basic sciences, that the nation continually goes on pouring resources into this area in spite of the evidence to the contrary. (Rolls-Royce's story, it may be said, is no accident.)

In this process, a number of technical colleges were developed by Lord Eccles as Colleges of Advanced Technology, and the Colleges of Advanced Technology, following Robbins, then became universities. Burgess and Pratt's story is largely the story of this conversion. They tell the tale very well, though it must be said that there is a fundamental distinction between history which reveals its sources and journalism which conceals them. Recent history falls heavily between these two stools, and there is reason to feel that another author might have told another story, and there is little available evidence to check which story was true.

There is no doubt the authors are correct about the chief features of the story. The conversion to university status was accompanied by a slowing down in the rate of growth which was also the result of the decreasing desire to study science and technology. The Colleges of Advanced Technology turned out to be very expensive per student place, and the process of conversion to university status was no easy matter. Burgess rather ruefully predicts that, given the class structure of English society, it is probable that the polytechnics will pass along the same road. If so, there are indeed many warnings in his book which need to be heeded.

JOHN VAIZEY

RACE RELATIONS

Race and Racialism

Edited by Sami Zubaida. (Explorations in Sociology.) Pp. xiii+185. (Tavistock: London and New York, October 1970.) 36*s* boards; 18*s* paper.

RACE relations research in Britain has been characterized until recently by the absence of a specifically "sociological" orientation. In the studies of prejudice and discrimination, racial conflicts were usually seen as the consequence of cultural clashes between the "host" and "immigrant" communities, and this tension was expected to disappear as the immigrants were gradually assimilated. But the exacerbation, rather than the lessening, of racial conflicts has undermined the validity of such assumptions, and necessitated a radical re-examination of the study of race relations.

This re-examination is the chief aim of *Race and Racialism*, a collection of seven conference papers by British sociologists. Sami Zubaida, in an excellent critical introduction, argues that research on racial and ethnic groups should define "their relationship to the wider social structure and the historical development of this relationship". One of the major problems is the definition of the key concepts in such an analysis, and the contributors themselves disagree in their exposition, for example, of "racism" and "racialism". Michael Banton, in his lucid paper, argues that because "racism" originated as a biologically based doctrine, sociologists mislead when they now use it to describe culturally based theories of racial inequality.

John Rex and David Lockwood both examine whether race relations situations demand a specific set of analytical concepts, or whether they may be defined as "class" situations using the categories of stratification theory. Rex, in his stimulating paper, constructs a typology of stratification situations in colonial and metropolitan societies, involving racial and ethnic groups. Whether or not these situations come to be defined as racial depends, he argues, on the existence of deterministic belief systems. Why "racist" ideologies develop where they do, however, still remains a question for future research.

Lockwood discusses the significance of the concept of

the "plural" society. Though one may disagree with some of the distinctions he draws between class conflict on the one hand and racial or ethnic conflict in plural societies on the other, his paper greatly illuminates the whole question of racial versus class consciousness and conflict.

Among the empirical contributions, that by Sheila Allen provides a good example of the integration of research in race relations with that in industrial sociology. She shows that the failure of the trade unions in Bradford to involve the lower skilled workers quickly became transformed into a racially defined conflict when the workers concerned were immigrants.

This book indicates that future research will move into more politically relevant areas—as social and economic structures become the objects of analysis. It also promises a more theoretical orientation in a field previously dominated by the British empiricist tradition. This book can be recommended to all who welcome such developments. JENNIFER HURSTFIELD

CARE OF SCHIZOPHRENICS

Institutionalism and Schizophrenia

A Comparative Study of Three Mental Hospitals 1960–1968. By J. K. Wing and G. W. Brown. Pp. xiii + 260. (Cambridge University: London, September 1970.) 75*s*.

THE authors of this book set out to evaluate the effects of the changing social milieu on hospitalized female schizophrenics. They describe their attempt as a search for "hard and obstinate facts" rather than for novel theories, and they have been successful. It is clear, as the authors point out, that all the polemic and propaganda for changes in hospital regimes and the real improvements that have occurred have been necessary from the point of view of humanity alone; but it is also pertinent to ask whether these changes have also resulted in the reduction of illness handicaps and in the encouragement of personal improvement. Their chapter on this area is a useful review of previous work.

Methodologically, the investigation rests on the firm basis of techniques the reliability and validity of which have been tested in earlier research. Assessments are made of the clinical condition of the patients and of the ward environments in which they live in three British hospitals. An attempt is made to show that certain "negative" aspects of the clinical condition, such as social withdrawal, are associated with the poverty of the social situation in which the patient finds herself. This hypothesis and numerous subsidiary ones are supported by a "cross-sectional" analysis of the patients and conditions in the three institutions. Advantage has then been taken of changes which occurred in the organization of their treatment regimes, during periods of four and eight years, to illuminate the problems of cause and effect in the associations established. Useful evidence, pointing to the efficacy of a richer social environment in evoking more positive behaviour, has certainly been forthcoming.

The work is liberally illustrated with clinical anecdotes and descriptive chapters on the wards studied. This produces a somewhat uneven texture in the book which is offset by the gains in understanding of the institutions and personalities concerned.

This is an essential text for anybody involved in the management of institutional care of patients. It gives a balanced view of the interaction between possible biological and social factors in the evolution of this particular condition but, more than this, it indicates the possibilities of stepping into natural experimental situations, and, with quite simple methods and analysis, achieving a rational assessment of the effectiveness of treatment ideologies. J. A. CLARKE

BUTTERFLY BEAUTIES

A Field Guide to the Butterflies of Britain and Europe

By Lionel G. Higgins and Norman D. Riley. Pp. 380 + 6((Collins: London, September 1970.) 42*s*.

AMATEUR and professional entomologists alike will we come this book for its authority, its thoroughness an at the same time its simplicity which enables even th beginner to identify rapidly the "rare" butterfly whic he finds in his garden. Furthermore, it encourages th young collector to want to know more about the way i which the scientific classification of species is organize(All the technical terms used are explained in a glossar and there is a separate check list of all the species as we as an index of English names. The last section contair nearly four hundred miniature maps indicating th localities in Europe where each species may be found.

The introduction, which contains general hints o collecting, might be thought rather old-fashioned by som experts, but, if so, it is to be looked on as a touch (old-world charm which serves to indicate the immens pleasure which two authors of riper years have derive from a lifetime spent in the study of butterflies. A speci feature of this book is the excellence of the illustration: Every species and many of the subspecies have a coloure illustration of both upper and underside, and of bot sexes. So often in natural history books one sees illus trations in which the artist has painted not so much wha he actually sees as what he thinks he ought to see an the result is often disappointing. In the young an talented artist Brian Hargreaves, the authors have a illustrator who attains the highest standard of butterfl pictures I have seen. Fellow worshippers of these gloriou insects will pray that he may be persuaded to devote hi life's work to painting the butterflies of the whole world Such a work would indeed be a major contribution t natural history.

In the text, each species receives about half a pag into which are tucked a description which notes all specia distinguishing features, the distribution and range, cater pillar food plants and the type of country where it i most likely to be found. Similar species which are mos likely to be confused are also noted.

Even for those with only a passing interest, this bool is a "must". E. R. LAITHWAITE

BREATHING REFLEXES

Breathing

Hering–Breuer Centenary Symposium. Edited by Rutl Porter. (A Ciba Foundation Symposium.) Pp. xiv + 402 (Churchill: London, 1970.) 80*s*.

IN April 1868, Hering described, with full acknowledg ment, work performed by his pupil Breuer entitled "Self steering of Respiration through the *Nervus vagus*". Late that year, Breuer published the full account of his worl on the reflex effects upon breathing which occur when th lungs of certain animals are inflated and deflated. Th inhibition of breathing which follows inflation of the lung has since become known as the "Hering–Breuer reflex" This was the first convincing demonstration in biology and perhaps in any discipline of what today would be called "feedback". It made a great impression on physiology and medicine and disturbance of this reflex was later to be invoked to explain a wide variety of respiratory disturb ance in disease. It is only in the past decade, however, that the reflex has been studied directly in man and its signifi cance and limitations in disease clarified. New reflexes arising from different receptors within the lungs have also been identified and their possible role in disease in place of the Hering–Breuer reflex considered.

The original aim of this Ciba symposium was to review and discuss this new work and its relations to other aspects of respiratory physiology and disease. But when it was appreciated that the meeting would coincide with the centenary of the publication of the Hering–Breuer reflex, the content and direction of the symposium were expanded and a most valuable biographical review and translation into English of the Hering and Breuer papers were added.

It is appropriate that the opening scientific contribution to the symposium compares the role of inflation reflexes in man and other animals. The remainder of the first section contains contributions on afferent nervous pathways including the sensory innervation of the airways and other reflexes from the lungs which are probably responsible for many of the effects which have previously been attributed to the Hering–Breuer reflex. These include receptors responding to changes in pulmonary interstitial pressure and others to mechanical deformation of the bronchi and bronchioles.

The second section of the book contains three contributions devoted to central interactions and peripheral motor mechanisms which consider the origin of the respiratory rhythm, neurological control in relation to metabolic and behavioural requirements and the variation of respiratory motor activity in relation to varying sensory inputs. The third section concerns respiratory sensation, the stimuli, receptors and pathways involved and possible psychological aspects.

The final section concerns the relationships of these physiological aspects to clinical problems including possible mechanisms of some respiratory symptoms, the relationship of respiratory frequency to breathlessness and the effects of vagal block on the sensation arising from pulmonary disease.

Although I found the symposium a most rewarding experience, it was also salutary to discover on reading the proceedings how much one had failed to appreciate at the time and how much more valuable it is to read the proceedings at leisure and digest the wealth of information and ideas that were discussed during those three days.

J. B. L. Howell

DERMATOLOGY OR BIOLOGY?

An Introduction to the Biology of the Skin

Edited by R. H. Champion, T. Gillman, A. J. Rook and R. T. Sims. Pp. x+450. (Blackwell (Scientific): Oxford and Edinburgh, 1970.) 85*s*.

For some years now there has been a growing tendency to introduce the word "biology" into all sorts of contexts where thirty years ago it had never set foot. A host of things which previously just existed are now credited with "biological significance", symposia and books dedicated to the biology of this, that and the other are currently fashionable, and we are even witnessing the germination of a crop of new bio-subjects. It is to be hoped that the widening and freer use of the word "biology" will amount to something more than lip-service and better than prostitution. I prefer to think it represents a public expression of a widespread sense of longing to get away from the lifeless world of test-tubes and slide-rules and "back to nature", which of course is not the same thing as "back to the trees". So intense is this longing that sometimes, as in this book, it gets ahead of itself and shades into wishful thinking.

This book is based on a postgraduate course of lectures which has been given at the University of Cambridge each year since 1963. As I have implied, the reason for its being written may be more encouraging than the book itself, which is unlikely to introduce anybody to the biology of anything, though one hopes it will not actually put anybody off. There are a few outstanding exceptions to the generally arid level of the book, particularly the chapters by Gillman on "Dermo-epidermal Interplay" and by Herbertson on "Inflammation", and the book should be read if only for the sake of these contributions. They and a few others are written about living processes as living processes, by authors whose approach to their subjects is that of the classically enthusiastic naturalist, a breed to which all true biologists have belonged and still must. These chapters and the motivation behind them would have been as welcome and comprehensible to Harvey or Pasteur or Darwin as they are to us. But these golden exceptions are few and far between in an otherwise lifeless desert of technological fluff and hack banality.

A number of the authors write as if they had just attended the course rather than given it. Some sound to be less than enthusiasts for their subjects, which they seem only to have mugged up for the purpose of filling the book. But the saddest group of contributions are those whose authors give the impression that their answer to the question "how does a seed grow into a tree?" would consist largely of a series of chemical formulae for the synthesis of chlorophyll and a page or two of equations. One can only assume that these two groups of non-biocontributors were press-ganged into the book because of shortage of local bio-talent.

The award for the most non-biological topic goes to chapter one on "Aspects of Mensuration", featuring a commendation of the new (SI) system of units (1 c.c. = 10^3 mm^3, and all that). The system is fairly thoroughly pilloried by its use throughout the rest of the book. If this kind of thing had to be included in a book about biology, surely its place was at the back of an appendix rather than as the opening chapter. The gold medal for the most unbiological remark in the book goes to the opening comment in chapter eleven: "Hair . . . was evolved to protect the skin against physical trauma, cold and ultra-violet light". No reference is given for the source of this instant, three-in-one resolution of a fascinating and perennially insoluble problem of cutaneous biology. Like all truly great gaffes this one's stature grows in the marvellous absurdity of its implications the more it is pondered: evolution by natural[3] selection[3] according to the SI system.

In short, this book might more truthfully have been entitled "A Young Person's Guide to Modern Investigative Dermatology". But the fact that it was called "An Introduction to the Biology of the Skin" shows that the authors wished it was. And full marks for that wish.

Ian W. Whimster

ASPECTS OF STEROIDS

Advances in Steroid Biochemistry and Pharmacology

Vol. 1. Edited by M. H. Briggs. Pp. xi+517. (Academic: London and New York, October 1970.) 150*s*; $21.50.

This volume, the first in a series, contains ten chapters devoted to various specialized aspects of the chemistry, biochemistry, physiology, pharmacology and analysis of steroids. It is not often that up to date reviews on such varied aspects of steroids are all found in one volume and for this reason alone the book will be a most welcome addition to a library or private collection. The editor has skilfully selected the topics so that the metabolism of steroids in man, animals, arthropods, marine invertebrates and plants is discussed.

There is much of interest here for the specialist in a particular field as for the beginner. Drs Vinson and Whitehouse review comparative aspects of adrenocortical function and, by way of introduction, devote some pages to a discussion of the methods utilized in a study of biosynthetic pathways, and explain how to interpret data

derived from kinetic studies—important topics which are often brushed aside too casually. The control of adrenocortical steroidogenesis is also considered and the possible mode of action of ACTH, the renin/angiotensin system and other regulatory mechanisms is discussed. Not least, this chapter concludes with an extensive table in which are collected a mass of data concerning adrenal steroid formation in a large number of species. Clearly, the authors are to be congratulated on their ability to review some 750 papers on adrenocortical function which have appeared during the past five years.

For many steroid laboratories the question "to automate or not to automate" is becoming increasingly important to answer. Drs Grant and Hall discuss the pros and cons of automation and give a critical survey of the various methods available for steroid analysis, pointing out which of these can be modified for automation. Dr R. D. Bulbrook reviews the mass of data now accumulated concerning the prognostic value of steroid assays in human breast cancer—a particularly welcome contribution in the light of the recent controversy concerning the value of the urinary discriminant. Other valuable chapters are concerned with the biosynthesis of sterols, the mode of action of insect hormones, the sterols of marine invertebrates and plants, the effects of steroids on tryptophan metabolism, cervical mucus and vaginal epithelium and the control of reproduction in farm animals.

It is to be hoped that the second volume in this series will attain the same high standard as this volume.

D. B. Gower

MOLECULAR IMMUNOLOGY

Biochemistry of Antibodies

By Roal'd S. Nezlin. Translated from the Russian by Michel C. Vale and edited by Fred Karush. Pp. xiii + 381. (Plenum: New York and London, 1970.) $25; 234*s*.

Anybody involved in teaching "molecular immunology" must have been faced with the difficulty of recommending suitable textbooks. This book is not the complete answer but it does provide a useful addition to the limited bibliography. No textbook in such a rapidly advancing field can hope to be up to date. In this case there is the added delay involved in translation of the original Russian text. The English edition has been updated by the author and also the original commentary has survived the test of the time lag very well. The methodological sections are lacking in current details; this in part must reflect the isolation of Russian science. But there is a good discussion of the methods covered. The physicochemical properties and structure of antibodies are well reviewed. The longest chapter on antibody biosynthesis provides a most welcome condensation of an extensive body of data and phenomena. From this background must eventually come an understanding of the immune response at a macromolecular level. This review could prove of value to the biochemist newly approaching antibody biosynthesis. The book closes with brief clear accounts of genetics and theories of antibody production.

There is, throughout, extensive referencing. Because of its origin the book contains many references to the Soviet literature which provide an interesting window on immunological studies in the Soviet Union even if those in Russian will be unhelpful to the majority of readers.

The translation is pleasing with an easily readable style and few ambiguities in the scientific English. The rare slip such as: "The allelic exception is also known not to apply to hemoglobulin" will cause more amusement than confusion. The general production standards deserve praise, particularly the clear attractive type.

This volume should prove of value to students, teachers and researchers embarking on, or engaged in, the field of immunology.

A. R. Williamson

RECENT SOIL STUDIES

Écologie Microbienne du Sol

By Yvon Dommergues and François Mangenot. F viii + 796. (Masson: Paris, 1970.) 180 francs.

This volume provides a thorough, up to date and int national coverage of information which is only otherw available from numerous monographs, journal artic and symposium reports. The 800 closely printed pag are grouped into five unequal sections. First, a systema account covers very briefly the principal groups microorganisms (bacteria, actinomycetes, fungi, alg protozoa and viruses). Then there is a long section deali with the effect of microorganisms on chemical process and cycles in the soil. This is followed by sections on t influence of physio-chemical factors on the microflo on interactions between microorganisms and vegetati and, finally, on interactions between the different grou of microorganisms.

The last section (reflecting, of course, today's inadequa understanding) is somewhat superficial and disjointe especially the brief sections on interactions with the s fauna. The penultimate section (interactions with veget tion) reflects the current preoccupation with *Rhizobiu* studies but is extremely brief on mycorrhiza. There i however, a useful section of about 50 pages on the prope ties of the rhizosphere.

The major biochemical section (part two) is writte chiefly by Dommergues and deals in turn with cycl of the major chemical elements (through carbon an nitrogen to iron, manganese and the like). Details a given of the principal intermediary compounds involve in decomposition processes, and there follows a fairl full discussion of recently explored topics such as humidif cation, the soil atmosphere, organo-metallic compoun and the effects of microbes on soil structure. Thus, most useful summary of some of the chief researc interests of the Nancy CNRS laboratory is placed in general context and made available to a wider audienc

The fact that I was periodically frustrated by th terseness of the treatment is less a reflexion on the write of the book than on the spectacular growth of soil micr biology over the past few decades and of the magnitud of the task undertaken. The authors have successfull assimilated the international literature and have provide an entry to the field for all who are interested in th ecology of soil. As a textbook of this kind it would hav benefited from a much fuller and more informative inde but it certainly deserves a wide readership and woul merit translation into other languages.

A. Macfadyen

OVERPRODUCTIVE LAKES

Eutrophication in Large Lakes and Impoundments

Compiled by C. P. Milway. (Uppsala Symposium, Ma 1968.) Pp. 560. (OECD: Paris; HMSO: London, 1970. 70*s*; 46 francs; $10; 37.50 Sw. francs; 30.40 DM.

The problems caused by the excessive enrichment o waters by fertilizers from sewage, industry and agricultur are world-wide. It is at last admitted by almost everybod that even the largest lakes should not be accepted a limitless repositories for rubbish. The Organization fo Economic Cooperation and Development (OECD) has bee collecting and collating facts about the problem for som years. This report is a valuable account of the situation i certain large lakes in Europe and North America, and in the Oslo Fjord. The first part, in English and French, dis cusses the aims and achievements of the symposium research and management, and matters discussed durin the meeting, together with synopses of facts about th lakes which form the case studies described in Englis

in the second part of the report. The lakes are Mälaren, Sweden; Neagh, Northern Ireland; Maggiore, Italy (with more than half the drainage basin in Switzerland); Constance (Bodensee) in the Federal Republic of Germany, Switzerland and Austria and the Laurentian Great Lakes of America. There are also shorter sections on Lake Lugano, Italy, and lakes in the Netherlands, and a note on the proposed Morecambe Bay Barrage.

Though much remains to be done, the scope of the investigations now under way and of the proposals under review offer hope for the future. Sometimes there seems to be a confusion of ideas and the verbosity of some parts of the report does not help. The book contains many signs of hasty production. From the title it seems that it is a compilation, which may explain the lack of editorship. Though rapid publication was needed, the secretariat of OECD should have done better in 18 months, especially with the help of the preprints it had before the symposium started. There are too many careless slips. Tables and figures may or may not be numbered and may or may not have captions. Photographs of lakes, some of which are very poor, appear once or twice without any indication of what parts of them and their surroundings are shown. In the text of the article on Lough Neagh references are given to published papers and unpublished documents in the usual way, but there is no bibliography at the end of the article.

J. W. G. Lund

WATER MEASUREMENT

History of Hydrology

By Asit K. Biswas. Pp. xii+336. (North-Holland: Amsterdam and London, 1970.) 117*s*; Hfl. 50; $14.

It is surprising that, for a science so basic as hydrology, this is the first book dealing solely with its development. Not that attention to the subject has been lacking, for there are quite a number of papers dealing with certain periods of progress and several books that attempt to cover the history of hydrology in a chapter or two. Now much of this material, and more unearthed by the author himself, has been brought together in a single volume. Here theories about the origins of springs and rivers can be traced from the age of Aristotle to the seventeenth century when Perrault, Mariotte and Halley scotched the concept of a subterranean cycle and, by experiment, confirmed the correctness of the pluvial theory. Ideas about the assessment of flow in open channels can be followed from the Romans' assumption that cross-sectional area of channel was the only control of discharge, to the last century when Manning devised his formula. Something can be learned of the development of instruments for determining rainfall and evaporation, and about the foundations of hydrogeology which are covered through mention of the works of Darcy, Dupuit and Forchheimer.

The book is well produced, written in an easy style and is adequately illustrated. More space could have been devoted to the period during the last century when the first country-wide instrument networks were being installed, and the role of the meteorologist in this development might have been mentioned. On the other hand, it is difficult to find errors of fact and omissions of references. One that could have been brought in was the answer by Barrington[1] to Heberden's (not Herberden) rainfall results from Westminster Abbey. Then there are some minor points like the Bishop of Llandaff becoming Llandoff, and hydrologic replacing hydrological, for which the author can be forgiven. But one thing that he should be aware of is the irritatingly short chapters that appear almost as inserts here and there and the rather arbitrary way that the chapters divide up rather than bring together the material he is presenting. Nevertheless, Dr Biswas should be congratulated for producing a volume of interest to all scientists concerned with water. He should also be congratulated in producing it since 1964—others might have spent a lifetime over the same task and achieved less.

John C. Rodda

[1] Barrington, D., *Phil. Trans. Roy. Soc.*, **59**, 359 (1769).

SUPERNOVAE BEFORE PULSARS

Supernovae and their Remnants

Edited by Peter J. Brancazio and A. G. W. Cameron. (Proceedings of the Conference on Supernovae, held at the Goddard Institute for Space Studies, NASA, 1967.) Pp. viii+240. (Gordon and Breach: New York and London, January 1970.) $21; 175*s*.

This book reports a conference which took place on November 2–3, 1967. In one respect this was a very unlucky piece of timing, just before the discovery of pulsars which are now widely accepted as supernovae remnants; but from another point of view this report is singularly important as a landmark in astronomy, neatly packaging the pre-pulsar knowledge of supernovae, and offering a chance of comparison between the theories held at the end of 1967 and the observations of new phenomena from pulsars which have been flowing in ever since.

The surprise which the discovery of pulsars caused is brought back to mind by A. G. W. Cameron's paper on the expected properties of neutron stars in which he concludes that "a neutron star will become a dead object rather rapidly", with the corollary that they would probably be undetectable.

The Crab Nebula is, naturally, the subject of a large portion of this volume, but there is a thorough discussion of other remnants in our galaxy and of supernovae seen in other galaxies, as might be expected from contributors such as Zwicky and Minkowski. The papers on theoretical models of supernovae explosions remain largely unaffected by recent observations, and still show some wide discrepancies between theories and observations. But the volume is of a generally high standard; all of the contributors are well known in their field, and the editorial work seems to have been unusually painstaking and accurate, many of the papers having been updated to some extent during the preparation of the book.

Although the gap between conferences and the publication of their proceedings seems to be increasing (and some proceedings would be better left unpublished), the unique position of this volume in the context of the revolutionary impact made on astronomy by pulsars ensures its historical importance, and its excellent presentation will make it widely used as a source guide of basic importance to both theoretical and observational astronomers.

John Gribbin

SPINS AND SOURCERY

Particles, Sources and Fields

By Julian Schwinger. Pp. iv+425. (Addison-Wesley: Reading, Mass., and London, September 1970.) 140*s*.

Professor Schwinger is well known, not only as the man whose Nobel prize-winning calculation of the anomalous magnetic moment of the electron is one of the great triumphs of relativistic quantum mechanics, but also as a lecturer of great flow and persuasiveness. His book reproduces on the printed page those carefully constructed sentences long familiar in the lecture hall, and the audience might be said to be represented by the odd character, Harold, who pops up from time to time to ask a conveniently leading question.

The eloquence is directed towards presenting an approach to relativistic quantum mechanics (elsewhere called by its author "sourcery"), which he believes is more satisfactory than either operator field theory on the one hand or analytic S-matrix theory on the other. It is better than field theory because it operates at the phenomenological level and does not pretend to know what the fundamental field structures are. Its superiority to S-matrix theory lies, it is claimed, in its taking space-time structure seriously with its notion of localized sources. The motto of the book is explicitly given as "If you can't join 'em, beat 'em". Nevertheless one cannot help feeling that in the end Schwinger has, in his own special way, joined 'em. The source picture is very similar to aspects of Feynman's space-time approach to quantum mechanics and it would require the arts of a mediaeval disputant to split the difference between a scattering skeleton and a Feynman diagram. All sensible relativistic quantum mechanics, whether field theoretic or S-matrix, keep this diagrammatic picture in view as a guide to their thinking, without believing that it is in literal detail the fundamental physical theory. There is a good deal more common ground than Schwinger suggests.

The book may be judged not only as an exposition of Schwinger's philosophical point of view but also as an introduction to relativistic quantum mechanics. In its favour from this point of view are the detail and clarity of the exposition. Less satisfactory is the insistence on the sourcery phraseology and the total lack of references. The book will be a useful source of information on higher spin formalisms and on gravitons. But (and here I fulfil a prediction by Harold that reviewers would complain of things left out) it is a pity that no hint of the power of dispersion theoretic methods is given. The complex plane has been a remarkable discovery (see p. 36).

J. C. POLKINGHORNE

COMPLEX FUNCTIONS

A First Course on Complex Functions

By G. J. O. Jameson. (Chapman and Hall Mathematics Series.) Pp. xii + 148. (Chapman and Hall: London, September 1970.) 30*s*.

THE author of this book has aimed at producing a thoroughly rigorous introduction to complex function theory, suitable therefore for undergraduates interested in mathematical analysis for its own sake rather than for its applications. Formally, the subject is attractive and easy, the difficulties chiefly arising from topological problems concerning the nature of the domains to which Cauchy's theorem applies. To turn these difficulties the theorem is proved for a triangle and extended to a star-shaped open set; this suffices for many purposes. To keep the book small, more advanced topics which are not immediate consequences of Cauchy's theorem, such as analytic continuation, Riemann surfaces, and the general mapping theorem, are excluded.

There are three sections. Basic theory comprises: the complex number field, making use of the concepts of a metric space; power series and the exponential function; and the definition of integration. Differentiable functions have a section which includes Cauchy's theorem, the residue theorem and the Taylor and Laurent series. The final section is chiefly concerned with the calculus of residues and particularly with the evaluation of real integrals by contour integration.

The undergraduate coming to this text may well have had some earlier heuristic and geometrical acquaintance with the complex variable. The bracing discipline of this lucid if austere account will, if he is to be a serious student of analysis, set him firmly on his road.

T. A. A. BROADBENT

Short Notices

Innocent Killers. By Hugo Van Lawick-Goodall and Jane Van Lawick-Goodall. Pp. 222 + 33 plates. (Collins: London, October 1970.) 45*s*.

THE Van Lawick-Goodalls have taken the unusual step of publishing original scientific research in the form of a book written specifically for the general public. It is unfortunate that this laudable attempt to bridge the gap between popular and scientific writing is not altogether successful. Lack of quantitative data and anthropomorphisms such as descriptions of animals as "resentful" will make the scientific reader uncomfortable. The standard of writing is patchy. Although the chapters on wild dogs and jackals, which contain straightforward accounts of observations of the behaviour of these animals, are very readable, the initial "background" chapter fails to be so. Nevertheless, in spite of these drawbacks, this book, with its exciting photographs, contains much of great interest about the lives and behaviour of some little-known animals.

Man's Ancestors: An Introduction to Primate and Human Evolution. By Ian Tattersall. (Introductory Studies in Biology.) Pp. 64. (Murray: London, October 1970.) 20*s* paper.

PALAEOANTHROPOLOGY may not be everybody's idea of a fast moving subject. Nonetheless, new discoveries of fossils and developments in dating techniques are leading to continual reappraisals of the steps of man's evolution, and up to date summaries of current thinking from time to time certainly help to link the new finds together. This new book, by Ian Tattersall, is a good example of the review required and students, in particular, should find it useful. Its one disadvantage is that the author seems a little unsure of his potential readership. He assumes only slight knowledge of animal classification, evolutionary processes and the geological timescale and therefore has introductory chapters on these aspects. On the other hand, without a glossary of terms or a labelled drawing of a human or primate skeleton or of a skull, he expects his readers to be acquainted with some quite complicated anatomical terminology. The large size of the book (29·5 × 21·5 cm) may make it awkward for the bookshelf, but it does allow for a more adventurous layout than is usual and photographs (of which there are plenty) and line drawings are shown to good advantage.

Carbon Fibres. Edited by Eric A. Smith. (Design Engineering Series.) Pp. 79. (Morgan-Grampian: West Wickham, Kent, 1970.) 55*s*.

IN any rapidly developing technological field there is often an acute lack of any overall state-of-the-art publication suitable both for the professional and the interested layman. This book usefully combines the two needs and covers many aspects of the production and use of carbon fibres and fibre reinforced materials. Each of the eleven chapters is written by authorities on carbon fibres drawn from industry, the world of engineering journalism, and the government departments and research establishments which have been connected with carbon fibre development. The editorial introduction points out that there is an inevitable overlap between chapters, but this is on the whole desirable because the reader is reminded from time to time of the important basic facts and figures. The appearance of rather unfamiliar abbreviations could, however, make it rather difficult to dip randomly into the book if one is a complete stranger to the subject. A useful bibliography is provided, together with a list of principal British manufacturers and suppliers of both carbon fibres and composites.

Correspondence

ESRO X-ray Astronomy Satellite

SIR,—I would like to comment on the proposal by the ESRO Mission Definition Group for a Lunar Occultation Satellite for high resolution studies of cosmic X-ray sources (*Nature*, **228**, 756; 1970). The authors imply that in order to determine positions of X-ray sources to arc seconds it is necessary to achieve inertial stability of the spacecraft to arc seconds. However, this is not the case; in fact, the positional accuracy achieved is typically a small fraction of the vehicle stability. As an example, for Sco X–1 an arc minute position was obtained from a sounding rocket whose pointing accuracy and stability were measured in degrees.

Formally the requirement to achieve high angular resolution is that one be able to reconstruct the inertial attitude of the vehicle on the same angular scale as desired for the X-ray observations. As an example, on NASA's HEAO, which will be rotating at a rate of 30 arc minutes per second, we expect to be able to determine instantaneous orientation to several arc seconds and locate X-ray sources to the same precision (*Nature*, **228**, 603; 1970).

There is a second requirement which has to do with the effective observing time per source; namely, that the vehicle pointing accuracy be sufficient so that the source can be acquired within the field of view of the X-ray instrument. This is readily achieved. Modulation collimators can be made to have fields of view of many degrees, and even focusing X-ray telescopes, unless they are designed to function at energies in excess of several keV, can have fields of view of a degree or more.

The techniques for accomplishing high angular resolution X-ray measurements are neither expensive nor complex, the principal requirements being large apertures and time resolution. The same considerations apply to high spectral resolution measurements as well.

Yours faithfully,

HERBERT GURSKY

Director, Space Research Division,
American Science and Engineering,
11 Carleton Street,
Cambridge, Massachusetts 02142.

Nocturnal Songbird Migration

SIR,—In their recent communication (*Nature*, **228**, 476; 1970) Gauthreaux and Able have reopened the question of whether passerine nocturnal migrants compensate for wind drift. They have shown that, in the southern United States, on a selection of seven nights in spring and five in autumn, birds flew almost exactly down-wind. Furthermore, on two nights when wind direction changed by about 70°, the migrants' flight directions also changed, so that they still flew down-wind. They propose that radar evidence[1] (including my own), which disagrees with the hypothesis that birds are drifted from a constant heading, refers not to songbirds but to shorebirds and/or waterfowl.

In England, there is no question of confusion between the radar echoes from small passerine migrants and those from waders and waterfowl. The former fly slowly (about 20 knots) and depart some 40 minutes after dark from the whole land-mass; the latter fly much faster (at least 30 knots) and depart 1–2 h before dark from discrete localities, usually on the sea-coast. If our interpretation of the radar evidence is incorrect, it is not because we have misidentified the major groups of bird species concerned.

Regrettably, Gauthreaux and Able's presentation does nothing to resolve the question of whether birds fly on chosen tracks or chosen headings. In the situation they have described—that of down-wind flight—these possibilities cannot be distinguished. Furthermore, it would have been useful to know what their migrants did on nights other than the twelve they selected. From my own data, it would also be quite easy to select twelve nights on which the wind coincided in directions with the migrants' tracks; but on many other nights the migrants' tracks followed similar directions even though the wind was partly cross or opposed to these. It was, in part, on this evidence that I concluded that migrants were not drifted from a fixed heading.

Finally, I remain to be convinced that the two instances of change in mean migration direction during the night with change in wind direction disprove the hypothesis that passerine migrants usually compensate for wind drift. Firstly, different birds are involved at different times of night. Might they not be different species with different preferred tracks? Secondly, we are not told exactly where the observations were made. If the spring observations refer to Lake Charles, Louisiana, then birds departing from the coast of the Gulf of Mexico at dusk and flying NE (some passing the observation point at 02.40 GMT) would all have passed well before the second set of observations were made at 06.20 GMT; so it may not be surprising that a different mean flight direction was seen at the later hour as it could have involved a very different group of migrants.

Yours faithfully,

P. R. EVANS

Department of Zoology,
University of Durham,
South Road,
Durham.

Biochemical Theology[1]

SIR,—

I have isolated from murine
Urine,
Collected from the Church or House
Mouse,
A substance which induces, by injection,
Reflexion,
Verbalization
And prognostication
(Sagacious
And, of course, efficacious).
Is this what makes Dr Crick
Tick?
If not,
What?

Yours faithfully,

A. G. OGSTON

Trinity College,
Oxford.

Obituary

James Fisher

JAMES FISHER, the ornithologist whose outstanding achievements as a writer, broadcaster and publicist did so much to raise the science of ornithology to its present status and popularity, and who was a prodigious worker for wild life conservation, died in a car accident on September 25, 1970. He was fifty-eight.

He was the son of a well known headmaster of Oundle School, Dr Kenneth Fisher, a keen ornithologist himself, and was educated as a King's Scholar at Eton and at Magdalen College, Oxford, where he graduated with first class honours in zoology. From 1936 to 1939 he held a notable post as assistant curator with the Zoological Society of London under his former teacher Julian Huxley. Throughout his career he was attracted to numerical data and maps and this, together with his interest in seabirds, led him on several expeditions to study the distributions of the Atlantic and Arctic seabirds. He led a team to assess the population of the Atlantic gannet and made a major study of the spectacular increase and spread of the fulmar from a sole colony on St Kilda to an extensive breeding range round the British coasts. His investigations took him repeatedly to remote islands and it was typical that he should have contrived to be lowered by helicopter on Rockall when he accompanied a naval party taking formal possession of the island for the British Crown.

It was the example he set by these studies and his first book *Birds as Animals* (published in 1939) that changed the ways of many bird enthusiasts and helped to make field ornithology the scientific discipline that it is today.

During the war his work took on national economic importance. In particular, his survey of the rook was valuable to the agricultural industry. Afterwards he turned to publishing and was associated with the production of the 'New Naturalist' publications, an outstanding series of works in natural history. He himself contributed *The Fulmar* (1952). He also became a publisher in his own right and was an advisor to and director of various publishing houses.

Of the many offices that he held in the field of nature conservation, he was at one time vice-chairman of the Royal Society for the Protection of Birds; he was honorary secretary of the British Trust for Ornithology during its formative period; and at the time of his death he was deputy chairman of the Countryside Commission and a member of the Survival Service Commission of the International Union for the Conservation of Nature.

Physically, James Fisher was a large man; he was a fine oarsman in his youth, winning the Silver Sculls in 1934. He was also a man of generous nature, never sparing himself either in his own pursuits or in helping others. His failing was a tendency to undertake more than anyone could achieve. He leaves his wife Margery, whom he married in 1936, their three sons and three daughters.

Announcements

University News

Mr M. J. Hamlin has been appointed to the newly established chair of water engineering in the **University of Birmingham.**

Sir F. Elwyn Jones has been elected president of **University College, Cardiff,** and **Professor L. A. Moritz** has been appointed vice-president (administration).

Mr Charles N. Myers, formerly executive associate with Education and World Affairs, has been appointed executive director of the Center for Studies in Education and Development, **Harvard University,** in succession to **Mr William R. Charleson.**

Dr F. D. Gunstone and **Dr. D. H. N. Spence** have been appointed to personal chairs in chemistry and botany, respectively, in the **University of St Andrews.**

Dr A. L. Walpole, a member of ICI Limited (Pharmaceutical Division), has been appointed visiting professor in the Department of Biochemistry, **University of Strathclyde.**

Miscellaneous

Dr D. Küchemann, head of the Aerodynamics Department, Royal Aircraft Establishment, has been awarded the **Ludwig-Prandtl-Ring** by the **Deutsche Gesellschaft für Luft-und-Raumfahrt.**

Dr J. H. Pearn, University of Queensland, has been awarded a **Florey fellowship,** to study the genetic aspects of some inherited children's diseases and to work on the fundamental pathophysiology of muscular diseases in children.

A **European Branch** of the **Environmental Mutagen Society** was founded earlier this year at Neuherberg and a council formed of representatives from various countries. Further information can be obtained from the secretary, Professor E. M. Cohen, Medical Biological Laboratory TNO, PO Box 45, Rijswijk 2100, The Netherlands.

Academician A. N. Tupolev, Sir Robert Cockburn and **Dr C. S. Draper** have been awarded honorary fellowship of the **Royal Aeronautical Society.** The British gold medal for aeronautics for 1970 has been

awarded to **Mr P. A. Hufton**, Royal Aircraft Establishment, and the British silver medal to **Mr M. J. Brennan**, Hawker Siddeley Aviation. **Mr Walter Tye**, Air Registration Board, has received the gold medal of the Royal Aeronautical Society, **Mr E. E. Marshall**, BAC, has received the Society's silver medal and **Mr N. F. Harpur**, BAC, the bronze medal.

Applications are invited from workers actively engaged on cancer research within a university department or research institute for travel fellowships to be awarded by the **International Agency for Research on Cancer** during 1971–72. The fellowships are intended to promote collaboration and consultation between institutions and are available for a maximum of three months, which may be spent at one or several different places. Further information can be obtained from the chief of the Research Training and Liaison Unit, International Agency for Research on Cancer, 16 avenue Maréchal-Foch, 69 Lyon 6e), France.

International Meetings

April 5–8, 1971, **Atomic and Molecular Physics,** York (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

April 14–16, 1971, **Electrical Conduction in Organic Solids,** Nottingham (Dr M. R. Willis, Department of Chemistry, University of Nottingham, University Park, Nottingham NG7 2RD).

April 26–28, 1971, **Frequency Control,** Atlantic City (J. M. Stanley, Solid State and Frequency Control Division, US Army Electronics Command, Fort Monmouth, New Jersey 07703, USA).

May 3–5, 1971, **Bioengineering,** Fort Collins, Colorado (Rocky Mountain Bioengineering Symposium Inc., PO Box 59, USAF Academy, Colorado 80840, USA).

June 3–4, 1971, **Molecular and Cellular Repair Processes**, Baltimore (Dr C. J. O'Donovan, Vice-President for Scientific Affairs, Miles Laboratories Inc., Elkhart, Indiana 46514, USA).

July 25–31, 1971, **Pure and Applied Chemistry Congress,** Boston (A. T. Winstead, c/o American Chemical Society, 1155 Sixteenth Street NW, Washington DC 20036, USA).

July 26–31, 1971, **Physics of Electronic and Atomic Collisions,** Amsterdam (Louise Roos, FOM-Instituut voor Atoom- en Molecuulfysica, Kruislaan 407, Amsterdam-Watergraafsmeer, The Netherlands).

August 1–6, 1971, **Immunology,** Washington (Secretariat, First International Congress of Immunology, 9650 Rockville Pike, Bethesda, Maryland 20014, USA).

August 2–4, 1971, **Olfaction and Taste,** Munich (Dr D. Schneider, Max-Planck-Institut für Verhaltensphysiologie, 8131 Seewiesen, Germany).

August 2–7, 1971, **Stochastic Point Processes,** New York (Dr P. A. W. Lewis, Mathematical Sciences Department, IBM Research Center, PO Box 218, Yorktown Heights, NY 10598, USA).

August 2–6, 1971, **Regulation of Food and Water Intake,** Cambridge (Dr J. T. Fitzsimons, Physiological Laboratory, Downing Street, Cambridge CB2 3EG).

August 16–19, 1971, **Spectroscopy,** Clayton (Dr J. E. Kent, Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia).

August 17–19, 1971, **High Frequency Generation and Amplification—Devices and Applications,** Ithaca (Professor Lester Eastman, Cornell School of Electrical Engineering, Phillips Hall, Ithaca, New York 14850, USA).

British Diary

Monday, December 14

Education and the Heavy Electrical Industry (6 p.m.) Professor G. H. Rawcliffe, Institution of Electrical Engineers, at the Queen's Building, The University, Bristol.

Electrical Research on British Rail (7 p.m.) Mr L. L. Alston, Institution of Electrical Engineers, at the College of Further Education, Crewe.

Materials for Piles (5.30 p.m., informal discussion) Institution of Civil Engineers, at Great George Street, London SW1.

Optical Studies of Adsorbed Layers at Interfaces (two-day symposium) Faraday Society, at the Royal Institution, 21 Albemarle Street, London W1.

Railway Breakdown Services (5.30 p.m.) Mr K. R. M. Cameron, Institution of Mechanical Engineers, Railway Division, at 1 Birdcage Walk, London SW1.

Tuesday, December 15

Application of Linear Induction Motors to High Speed Transport Systems (6 p.m.) Professor J. M. Barwell, Institution of Electrical Engineers, at the Carlton Hotel, Edinburgh.

Chocolate Fats (6.15 p.m.) Dr G. R. Howat, Society of Chemical Industry, Food Group, jointly with the Oils and Fats Group, at 14 Belgrave Square, London SW1.

Drive and Control Systems for Large Satellite Tracking Antennae (6.15 p.m.) Mr B. R. Tuppen and Mr J. B. Owens, Institution of Electrical Engineers, jointly with the Institution of Mechanical Engineers, at Lanchester Polytechnic, Eastlands, Rugby.

Electrode Kinetics and Processes Involving Solid Electrolytes (one-day meeting) Society for Electrochemistry, Solid State Sub-Group, in the Metallurgy Department, Imperial College, London SW7.

Micro-circuits, Noise, Sequential Control and Mechanised Assembly (6.30 p.m.) Mr A. Pugh, Institution of Electrical Engineers, at the University, Nottingham.

Noise—Some Aspects on its Measurement and Control (2 p.m., symposium) Society of Environmental Engineers, in the Mechanical Engineering Department, the University, Birmingham.

Severnside of the Future (5.30 p.m.) Mr A. V. Hooker, Institution of Civil Engineers, at Great George Street, London SW1.

The Polar Ionosphere and the Magnetosphere (10 a.m., discussion meeting) Royal Society, at 6 Carlton House Terrace, London SW1.

The Role of the Buying Activity and Buying Policy in the Process Engineering Industry (6 p.m., discussion) Institution of Mechanical Engineers, Process Engineering Group, at 1 Birdcage Walk, London SW1.

Thyristor Engineering (6.30 p.m.) Mr D. B. Corbyn, Institution of Electrical Engineers, at Hastings College of Further Education, St. Leonards on Sea, Sussex.

Wednesday, December 16

Designing War Ships for a Cost Effective Life (6 p.m.) Vice-Admiral R. G. Raper, Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1 (Charles Parsons Memorial Lecture).

Distribution (symposium, 2.30 p.m. to 8.30 p.m.) Institution of Electrical Engineers, at Lanchester Polytechnic, Eastlands, Rugby.

Modern Developments in Titanium (7.30 p.m.) Mr G. Willison, Oil and Colour Chemists' Association, at the Carlton Hotel, North Bridge, Edinburgh.

Telemetry (7.30 p.m.) Mr R. E. Young, Institution of Electrical Engineers, at Inverness Technical College, Inverness.

The Design of Amplitude-Phase Modulated Pulse Sequences for Radar (6 p.m.) Mr M. H. Ackroyd, Institution of Electronic and Radio Engineers, Aerospace, Maritime and Military Systems Group, at 9 Bedford Square, London WC1.

Thursday, December 17

Additives in Iron Ore Pelletizing, Dr D. F. Ball, Mr P. R. Dawson and Dr J. T. Fitton; **Estimating the Stability of Excavated Slopes in Opencast Mines,** Professor E. Hoek (5 p.m.) Institution of Mining and Metallurgy, at the Geological Society, Burlington House, Piccadilly, London W1.

511th Meeting (two days) Biochemical Society, jointly with the Association of Clinical Biochemists, at the Royal Postgraduate Medical School, Hammersmith Hospital, London W12.

Friday, December 18

164th Meeting (two days) Genetical Society, in association with the Population Genetics Group and the Fisher Memorial Committee, in the Botany Lecture Theatre, University College London, Gower Street, London WC1.

DECEMBER 26, 1970

Putting Down More Aircraft

THE first thing to say about the summary of the report of the Roskill Commission on the siting of the third London airport is that the Minister of Trade and Industry, Mr John Davies, has been sensible in persuading his officials to make the decision known before the report in full could be published and that, to judge from the small sample of its work now available, the Roskill Commission has been as thorough and lucid as its earlier publications have tended to suggest. The second thing to say is that the decision, to build an airport at Cublington, nearly 50 miles north-west of London, is probably wrong. Indeed, the summary of the report now made available suggests that the commission found it hard to decide between Cublington and the quite different site at Foulness, farther away from London to the east on the Thames estuary. One of its members, Professor Colin Buchanan, has actually chosen to dissent from what the majority of his colleagues recommended, and has plumped for Foulness as the most advantageous site. Most probably, the government will be hard pressed to know precisely what to make of the Roskill recommendation. Plainly there is at least a chance that the recommendation to build at an inland site will be discarded.

The commission says that there is no ideal site for a new London airport but that, of course, is a truism. In the siting of all kinds of public facilities, from supermarkets to sewage works, decisions must be compromises. Inevitably, airports bring noise to people living nearby, many of whom never leave the ground. Airports also bring traffic, from which local inhabitants suffer without profit. Without careful planning control, airports can also become foci for rapid industrial development, with the result that isolated parts of the country can be turned into eyesores. The list of complaints against airports is indeed so long and easily extended that it is tempting to wonder how they are ever built. The truth is, of course, that they are necessary as well as being potential nuisances. Civil aircraft are not merely for the jet set. Without them, commerce would be greatly hampered; without easy access to them, prosperity would be diminished. Judge Roskill and his team have made it plain that their choice must be an unpleasant compromise and they reject what might be called the Luddite view of modern airports—that they should be done without. That is a good beginning.

The commission seems also to have rejected the argument that its objective should be to devise a strategy for the development of an airports policy for the United Kingdom as a whole and, to the extent that this view is to be accepted in its broadest sense, the commission is right. Instead, it claims to have been guided alternately by the doctrine that the airport should be sited in the way that makes the best economic use of the investment which its construction will entail and the view that it should be put where it will be most helpful for the forward planning of national resources. All this is sensible enough, but in taking what may be called the narrow view, the commission has overlooked considerations such as the importance of siting airports in such a way that air traffic considered as a method of linking one place with another is most efficient. It has forgotten what it is fashionable to call the systems approach. If the summary now issued is not a travesty of the full report, there is no mention in the detailed discussion of where to put the airport, of the kinds of aircraft that will be using it and of the extent to which the journeys they are likely to be making will be affected. Instead, the commission seems to have fallen into the familiar trap of giving most attention to that part of the entire air journey which can be most closely analysed and which is of most immediate local concern—the journey from the airport to its parish. By doing so, it may have chosen a site but it has missed an opportunity.

The choice between Foulness and Cublington is Occam's Razor stuff. In the end, the Roskill Commission seems to have been frightened off by some of the drum-beating with which several development companies and hastily formed consortia threw themselves into the business of planning industrial developments on the north side of the Thames to surround and no doubt stifle the putative airport at Foulness. With justice, the commission is correct in rejecting the view of some capital developers (the Thames Estuary Development Company in particular) that there would be advantages in financing the whole operation with private capital—with a project of this size, no government could let its *rentiers* go bankrupt. But there are great benefits in any scheme that proposes to turn mud into dry land, and those who complain that Britain is already overcrowded must surely now be disappointed that several square miles of Buckinghamshire are to be covered with concrete if the Roskill Commission has its way. As well as such intangible benefits, however, Foulness is also admitted by the commission to be the least affected of any site at sea level by cloud, the least offensive to those with good planning at heart, the least likely to disturb dwelling-places and amenities, although it must, to be fair, be acknowledged that coastline of a kind would be consumed. The commission even says that an airport at Foulness would cause less indirect disturbance by requiring the construction of roads in inconvenient places, that it would fit in well with the pattern of minor airports around London

(while Cublington would put an end to flying from Luton), that it will cause less noise and that there is no technical barrier to its construction.

So why then settle for Cublington? The Roskill Commission says not merely that Foulness is comparatively inaccessible but that inaccessibility will breed disuse so that twenty years from now air passenger traffic through Foulness would be 12 million a year less than through one of the inland sites. It will be interesting to see, when the full report is published, how the commission arrives at this conclusion. It might have been thought that the usability of Foulness and therefore the traffic through it, like the usability of an airport elsewhere, would be determined by the ease of access. In the event the commission rejects the notion that there should be a high speed link by rail between London and Foulness on the grounds that a comparatively high fare could not be justified commercially, but this is yet another point on which only the full report will be able to throw light. Did the commission adequately discount the fact that an air traveller who has paid tens of hundreds of pounds for a ticket may be willing to stomach a few extra shillings for ground transport if the service is better? This is one crude representation of the systems approach. It is a pity that the Roskill Commission had not been indoctrinated by the cyberneticists. In the event it argues as if it has been living in the shadow of the economists—it claims that over the life of the airport, Foulness would consume national resources worth more than £100 million. This sum of money may be large compared with the cost of laying down a single runway, but in these sophisticated days everybody knows that this is not the critical parameter. What matters is the properly discounted and aggregated amount of money spent on construction, operation, maintenance and access. But this sum for any airport is likely to be merely peanuts compared with the equivalent economic value of operating aircraft likely to use the third London airport. In circumstances like these, the difference of £100 million which Judge Roskill has identified is not seriously to be counted an impediment to building at Foulness. Mr John Davies should feel quite free to say that the nuisance value of the noise that an airport built at Cublington would cause, when properly discounted and aggregated over thirty years, would be much greater than this figure. The hope then is that the Roskill report will be valued as a sensitive analysis of an important problem and that its recommendation will be politely discarded in favour of an airport in the Thames estuary with a fast rail link on the ground and hardly any noise.

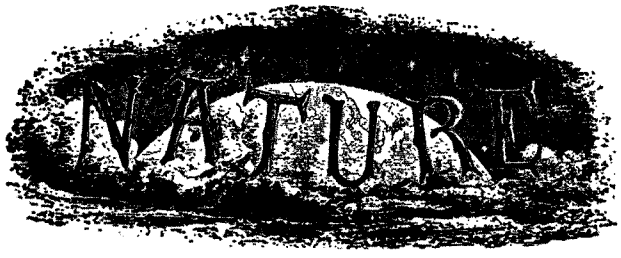
In passing, the Roskill report has quite discredited the British Airports Authority, which is something to be grateful for. Over the years, Mr Peter Masefield and his colleagues have been representing that the existing airports would be choked solid with aluminium alloy and people unless work had begun on the third London airport a year ago. What the commission asks for is that the first runway of the third large London airport should be functioning in 1980 or soon afterwards. If Mr Masefield had been taken seriously, in his protests at the abandonment of the foolish site at Stansted, the United Kingdom would have ground to a halt long before then. Sensibly, Judge Roskill, who earns his living in the judicial system and not the management of airports, has nevertheless the acumen to see that there is plenty of scope for the further development of airports such as Luton and Gatwick, and for the imaginative exploitation of computer sequencing as well. The implication, then, is that there is plenty of time for careful study and reappraisal of the commission's work, and every opportunity for the present government or even its successor to agree with Professor Buchanan that Foulness is by far the best choice for a third airport. After all, nobody can tell just what the pattern of traffic within the United Kingdom will be in 1980, or whether the distribution of population will be radically different from what it is at present. The Roskill report, in other words, promises to become as much a conversation piece as a turning point in the history of air transport in Britain. It is therefore important to remember that it is also a monument to the efficacy with which common sense and public protest were able to overturn the previous government's reckless acceptance of its officials' devotion to the site at Stansted.

Chemists are Like Dodos

THE Royal Institute of Chemistry's committee under Professor Colin Eaborn (see page 1244) has produced one of the most profoundly conservative documents to have been published in the modern history of higher education. With touching devotion to the belief that chemistry is not so much a discipline as a virtue, the committee proclaims the advantages of the present system for training chemists at British universities, deplores the way in which students appear to be increasingly unwilling to exploit these advantages, bemoans the difficulties which beset chemistry graduates seeking jobs and then hopes—its recommendations are hardly better—that by some magic everything will come right. In much the same spirit, no doubt, the last of the now vanished quill pen manufacturers must have wrung their hands in bewilderment over the falling away in trade. Are not our quill pens as good or even better than ever? Is it not mere fickleness and even fecklessness that has driven the customers away? And will not everything be right again if we hang on (with government subsidies to help) waiting for other people to change? This, at least, is what the least adventurous among the quill makers would have said—their more farsighted colleagues would have been investing heavily in the manufacture of steel nibs. The danger now, in British chemistry, is that Professor

Eaborn's report will serve only to undermine the flickering resolution of those who may have considered that the time is right for change.

The object of the exercise was meant to be a study of the relationship between university chemistry and the needs of British industry. Fair play, Miss Elizabeth Paul, who was charged with making the survey of opinion among chemists, teachers and industrialists, has done a splendid job which throws a good deal of light on the sociology of industrial chemistry in Britain and which at the same time provides much evidence to contradict some of the committee's generalizations. The attitudes of chemistry students and recent graduates to their undergraduate education should have been a warning, for example. In the survey which Miss Paul has carried out, 72 per cent of undergraduates and 64 per cent of postgraduates considered that undergraduate courses required too much learning of factual material and 59 per cent of undergraduates and 57 per cent of postgraduates considered that ancillary courses should have been better linked to undergraduate chemistry. Most students expressed a need for more tutorials and seminars, more theory, less rote learning and less work. Miss Paul says that "the complaint most relevant to our inquiry relates to the breadth of the subject matter covered . . .". The same survey has revealed that most of those who graduate as chemists are dedicated to Professor Eaborn's monasteries before leaving school, thus confirming the common belief that chemistry departments at British universities are more exacting in their requirements of intending students than most other kinds of science departments. In circumstances like these, nobody will be surprised that "students, university staff and industrial employers and employees would welcome some broadening of university courses (in chemistry)". Indeed, the only puzzle is that the Eaborn committee should dismiss the case for a broader education without much concern for argument one way or the other.



On the internal organization of chemistry courses, for example, the committee argues quite sensibly for a balance between basic and vocational training (and in particular between theoretical chemistry and practical chemistry), but then goes on to dismiss at least some of the complaints of those who consider that chemistry teaching should be more modern and lively with the cheap canard that "many of the students who do not do well in examinations are unlikely, on looking back, to express enthusiasm for their course". Is this belief compatible with the conviction among undergraduates and postgraduates alike that chemistry entails too much rote learning, for example? On the more general issues of whether undergraduate courses for chemists and other scientists at British universities should be leavened with other elements, the committee is at its most iconoclast, specifically taking issue with the Swann committee which two years ago put forward the belief that more general education would imply that graduates would be more adaptable to the needs of industry, chiefly on the grounds that the industrialists responding to questionnaires did not rank this high among their complaints. It may of course be true that "employers selecting chemists much prefer to recruit special rather than general degree graduates", but is it really in the best interests of the students that the opinions of potential employers on these questions, often based on misconceptions, should determine the character of the undergraduate curriculum? And is it right that the committee should respond to the general feeling among chemists and their employers that a capacity to write literate reports would be an asset by, first, woodenly proclaiming that "we cannot recommend that a formal course in report writing and the use of English should form part of all chemistry degree courses", in the process passing the buck downwards to the secondary schools where "basic command of correct English must be acquired" and upwards to induction training on the grounds that "it is at this stage that the student will recognise the importance of report writing to his career and so be influenced to give his mind to it"? The issue is not whether chemistry graduates should be taught to write after having been taught chemistry, but whether they should be educated in such a fashion as to be literate. On the similar complaint from industry that chemistry education should deal more explicitly with commercial applications of research and with techniques such as those of operational research, the committee takes the line that there is no time for luxuries like that, and that, in any case, undergraduates might be taught things not strictly relevant to their later life. In this spirit were those apprenticed to quill makers no doubt discouraged from worrying about metalworking.

The truth is, of course, that undergraduate education at British universities in chemistry is—with few exceptions—notoriously narrow and narrowing. The fact that the committee has discovered with understandable alarm that students drift away from chemistry after one or two years at those universities where they have the chance is one practical sign of trouble. Another is the way in which chemistry departments are hard pressed to fill their vacant places with suitable candidates. In circumstances like these, the committee's complacency about the present state of affairs is in the interests neither of chemistry nor of those students who are recruited to the cause. At the very least, the Eaborn committee should have considered in some detail the issue which it has studiously ignored that there should be a radical reconstruction of the pattern of undergraduate teaching in Britain, possibly with a period of more general education leading into one more concerned with specialized and vocational matters. But even within its chosen terms of reference, the committee should have paid serious attention to the problem of how to impart vitality and relevance to the teaching of chemistry at British universities.

Because of its internal defects, the committee's report is less convincing than it might have been in its largely sensible account of how relationships between chemistry departments and industry might be more efficiently regulated. One conclusion that deserves some publicity is, however, that the belief among

students of chemistry that industry is less likely to provide challenging opportunities for advancement than popular legend would suggest is exaggerated. To be sure, those already at work find their will to contribute to the commercial success of their enterprises frustrated, but it is not entirely clear whether these complaints arise from the unfamiliarity of work to those recently accustomed to academic life or from defects in the way in which industry itself is organized. In reality, the committee recognizes, the chemical industry is unusual among British industry in its willingness to support teaching programmes at universities, schemes for the encouragement of research and even relationships between undergraduates and potential employers. Whether it is sensible that there should be a standing committee of chemistry professors and representatives of the Chemical Industry's Association is another matter—this sounds too much like too much bureaucracy. But there is something to be said for some means by which university chemistry departments and the potential users of their product could work out the reform of chemistry teaching at British universities which the Eaborn committee has avoided.

100 Years Ago

NATURAL SCIENCE AT OXFORD

THE progress which Natural Science has made at Oxford within the last few years has far exceeded the anticipations of even the most sanguine of its promoters. It is but ten years ago that the New Museum was opened, and not much longer since the School of Natural Science was founded. Since then, year by year, the interest shown in these studies has steadily augmented, the number of undergraduates attending the University College Science Lectures has augmented in proportion as the number of these lectures has increased, and the School of Natural Science has become recognised as on a par with the other three great schools of Philosophy, Mathematics, and Law and Modern History. This has been chiefly brought about by the high standard of excellence required by the examiners in this school. When the position taken by Natural Science at a university which has commonly been condemned for neglecting this very subject, is fully recognised outside its own walls, there can be no doubt but that a far greater number than at present will come up to Oxford to pursue their science studies there. Hence it may not be here out of place to give as briefly as possible a short *résumé* of the opportunities held out to Natural Science students at Oxford, in the way of university and college lectures and the various scientific museums and libraries, as well as to notice the numerous rewards and honours which are open to all such students. To do this completely would far exceed the limits of this article, so that what follows must only be taken as a sort of index, as accurate as possible, to a subject, the details of which can be obtained by writing to the tutors of the various colleges mentioned.

From Nature, **3**, 170, *December* 29, 1870.

OLD WORLD

RESEARCH POLICY

Another Fresh Look

THE Council for Scientific Policy has embarked on a study of the pattern of expenditure in civil research, supported by the Department of Education and Science, and of the arrangements which at present exist for carrying out this work. For this purpose, the council has set up a working group under its chairman, Professor F. S. Dainton. The group is to examine the structure of the research councils and the relationship between them as well as the functions of the University Grants Committee in relation to research and the work of other public bodies and government departments with interests in civilian research and development.

The working group has been set up by the CSP on its own initiative and will provide advice to the Secretary of State for Education and Science, Mrs Margaret Thatcher. Typical of, although not prominent among, the questions to be considered is whether the Agricultural Research Council should continue in its present relationship with the Department of Education and Science or whether, alternatively, some of its functions and interests should be transferred to the Ministry of Agriculture, Fisheries and Food. (The notion that something along these lines should be done has for a long time been cherished in some Whitehall offices.) In this sense, the Council for Scientific Policy's working group will be complementary to the review of government policy on all kinds of research and development entrusted to Lord Jellicoe. Although the starting point for much of the CSP's work will be an attempt to establish criteria for assessing the social value of particular activities in research and development, so that the report may deal with matters such as research policy in fields such as telecommunications and transport, Lord Jellicoe's study will cover defence research as well. By all accounts, the CSP study may be complete within three months, in which case it should be well timed to play a part in the larger review of research and development policy to be expected later in 1971.

CHEMISTRY

No Formula for Change

by our Education Correspondent

A SORRY tale of a declining proportion of the most able students being attracted to university chemistry courses and of poor prospects for chemists in the job market is told in a report published this week by the Royal Institute of Chemistry. Based on a four-year study conducted by a committee under the chairmanship of Professor Colin Eaborn, professor of chemistry at the University of Sussex (report of the *Committee of Enquiry into the Relationship between University Courses in Chemistry and the Needs of Industry*, Royal Institute of Chemistry, £2), the report shows that chemistry departments are accepting about 80 per cent of the candidates who apply. Bearing in mind that about 20 per cent of all candidates who apply to universities through the Universities Central Council on Admissions fail to achieve the minimum entrance qualification of two A-level passes, this finding suggests

that chemistry departments are scraping the barrel to fill available places. Nevertheless, in all the four years which came under the scrutiny of the committee, university chemistry places were left unfilled. This state of affairs, the committee suggests, "is a matter of concern for the country in general and for the chemical profession in particular".

But the number of chemistry graduates likely to be produced by the universities during the next few years will not fall much short of Britain's requirements for specialist chemists. Chemistry graduates have consistently formed the largest proportion of unemployed scientists six months after they have graduated, and this factor has led to suggestions that output from university chemistry departments is already too great to be absorbed by industry. But the committee takes a different view. It suggests that one of the chief troubles is that too few chemistry graduates are accepted for jobs in management, administration, government and politics, and it points out that the situation in Britain is very different from that in the United States, where only half the chemistry graduates take up jobs specifically requiring chemical knowledge.

It is therefore surprising to find that the report pours cold water on the idea that chemistry courses should be despecialized—the committee has some sharp words to say about the suggestion canvassed in, for example, the Swann report, that graduates would be more useful to industry if they had studied a wider range of subjects to a less advanced level than is now customary in special degrees. "We do not accept that any possible gains would outweigh the loss of professional competence in the subject of specialization," the committee maintains, and moreover "we encountered no clear opinion in the chemistry industry as a whole that the present degree courses in chemistry are too specialized."

What, then, is to be done? The committee suggests that, for one thing, chemistry courses tend to involve "too much learning of facts", and it suggests that chemistry teachers should consider ways to get round this. There is also a suggestion that chemistry students should be given the option of studying courses such as economics, sociology and computer programming. But such courses should be available only as subsidiaries and should not dilute the specialist nature of the major chemistry course.

The committee is satisfied with the proportion of undergraduates in chemistry departments who intend to take up careers in industry, and it also suggests that employers are satisfied with the graduates they get. But the proportion of graduates entering teaching is another matter. The committee believes that it is "unfortunate" that the teachers must now have teacher training qualifications before they can take up school teaching, because this restriction is likely to deter the more able graduates away from the schools. A means of offsetting this deterrent should be found, the committee urges, and as a minimum, grants for the compulsory training year should be equivalent to those for PhD students.

As far as PhD courses in chemistry are concerned, the committee is generally satisfied: "We believe that existing PhD courses provide a good preparation for chemists who will take up research careers, including those who will move to non-research posts after a few years in industry". Nevertheless, the committee recommends that some variants of the normal PhD course should be introduced. One suggestion which is canvassed in the report is that PhD courses could combine the equivalent of two years' chemical research with one year of formal instruction in, for example, technological economics, business management, operational research or marketing.

The committee therefore sees room at postgraduate level for undoing some of the effects of specialization at earlier levels, but it has few formulae to offer for changing university chemistry education. The report is, on the whole, a depressingly conservative document.

ATOMIC ENERGY

Turning Point for Dragon

WITH the first commercial application of the high temperature reactor (HTR) in the offing, the emphasis of research in the OECD Dragon reactor project has shifted steadily away from reactor development to problems of high temperature fuels and of control systems. The annual report of the project up to April 1970 shows that expenditure on reactor construction continues to diminish in an overall budget which rose by more than 12 per cent last year compared with 1968/69. Growth is unlikely to continue beyond 1971, however, and spending should fall below the present level by the time the agreement between the twelve countries involved expires in 1973. The expenditure in 1969/70 of £2.3 million brings the total cost of the project since its inception eleven years ago to just over £31 million.

A chief part of the Dragon programme is now centred on the use of the 20 MW experimental reactor at Winfrith as a test facility for industrially developed high temperature fuels. Previous work on the properties of coated fuel particles compacted in graphite matrices has been extended to include the testing of complete fuel assemblies suitable for use in future power stations. Among the recent innovations is the introduction of fuel elements in the form of large blocks of graphite with machined holes to carry tubular pins.

During the period covered by the report, the reactor was shut down for the fitting of new heat exchangers and secondary circuit pumps to increase the heat removal capacity. Although most of the work in the Dragon project is now centred on the testing of fuel and core materials, the approach of the first contract for an HTR for a power station—probably for Oldbury B—has focused attention on a host of important secondary problems affecting the HTR. The design of heat exchangers, gas circulation pumps and control systems are prominent among these. The chemical interactions between the graphite and the helium coolant are being studied as well as systems for monitoring and maintaining the purity of the coolant.

Various safety tests have also been carried out to ensure that the leak detection system for the pressure vessel is adequate for commercial usage. New information on the fracture mechanics for partially penetrating cracks has led to fresh studies of the detection system but the equipment was found to be quite efficient enough to reveal a crack before it reached anywhere near its critical length under the operating conditions of the vessel.

GENERATORS

Some Light in the Gloom

THE Central Electricity Generating Board can take a crumb of comfort from the fact that the troubles with its 500 MW generating sets, which last December caused power reductions of about 6 per cent, are being resolved. And prospects for the smooth installation and commissioning of some of the 660 MW sets in the next few years are good. But by no means is everything in the garden now rosy. Other breakdowns and troubles last winter pushed the proportion of plant which was out of operation at critical times to over 20 per cent (*Nature*, **228**, 1125; 1970) and the shortage of smokeless fuel will not make things any easier for the rest of this winter.

The whole matter of the 500 MW sets was reviewed by the Select Committee on Science and Technology earlier this year (HMSO; 4*s*) and the conclusions were that the design work was insufficiently detailed, that there were welding defects and hairline cracks in the boilers and that some malicious damage had been done.

There are now twenty-three 500 MW sets at various stages of commission and some are producing over 95 per cent of their maximum power—the outputs vary from about 280 MW to 480 MW. Three of the four sets at Eggborough, Yorkshire, which contributed much to the trouble last winter have now been modified and are generating between 380 and 430 MW each; the fourth is being reconstructed. There has been no recurrence of the damage at Aberthaw B power station which was considered malicious by the Select Committee because a number of bolts were found inside the generators.

Manufacturers seem to be taking to heart the remarks about design contained in the Select Committee Report and the CEGB is confident that the 660 MW sets to be incorporated into the Hinckley Point B, Hartlepool and Dungeness B nuclear power stations will not show the type of fault which beleaguered the 500 MW sets. The board points out, however, that final tests can never be carried out until the sets are in position.

VENUS-7

Mystery and Speculation

from our Soviet Correspondent

THE degree of success of the Soviet Venus-7 probe would seem to have added a further, if minor, mystery to that already mysterious planet. There has been considerable speculation about whether the probe was intended to reach the surface of the planet in a viable condition and, if so, whether it succeeded. The relatively minor announcement for Venus-7 in *Pravda* (December 16, 1970)—a small article half-way down the front page, with no supporting articles in the inside pages—suggests, perhaps, that Venus-7 cannot yet be described as a major Soviet success in space research. The facts of the probe's mission, however, seem to be as follows.

Venus-7, launched on August 17, 1970, completed its 320 million km journey in 120 days, during which it had broadcast to Earth 124 sessions of telemetered information. Preparations for the descent began on December 12 at a distance of 1,300,000 km from the planet. At this point, the batteries for the descent stage were switched into a charging circuit from the solar cells. At the same time, cooling of the descent stage to a temperature of $-8°$ C began.

Immediately before entry into the Venusian atmosphere, the descent craft was separated from what is described as the "orbital section". The descent craft entered the atmosphere at 10·3 km/sec and this velocity was reduced by aerodynamical braking to 250 m/sec when the parachute system came into operation. The antennae were deployed and radio transmission of information began.

The transmission continued for 35 minutes. Until some preliminary results are released, whether the descent stage actually reached the surface of the planet, or whether it, or its transmitting system, was destroyed by heat while still parachute-borne is open to speculation. It is perhaps significant that, in the preliminary news releases from the TASS agency, the concluding stage of the experiment is described as "entry into the atmosphere", and no mention is made of any possible contacting of the surface.

CANCER THERAPY

Insufficient Evidence

THE publication last week by Dr Joseph Issels of a preliminary report of his unconventional method for treating cancer has done little to remove the controversy surrounding his techniques. The Medical Research Council's Joint Coordinating Committee on Cancer Research was quick to publish a statement pointing out that the evidence so far available is "insufficient to enable a scientific assessment to be made of Dr Issels's methods of treatment or of his results", and the committee added that such evidence as there is does not encourage the belief that any advance in the treatment of cancer has been achieved. The committee, nevertheless, intends to send a few experts to have a look at Dr Issels's clinic at Ringberg to see whether further study of his methods is necessary.

In several respects, Dr Issels's report of his work, published in the latest issue of *Clinical Trials Journal*, leaves unsaid more than it reveals. To be fair, Dr Issels himself claims that his results are not conclusive, and that a more detailed statistical investigation of the results of his technique should be made. He describes in his article a study of a sample of 242 from a total of 750 patients who attended his clinic. It turns out that 42 from the sample were alive and "fully fit for work" five years after treatment, and, of these 42, 39 still showed no signs of cancer 15 years after treatment. A preliminary study of a further 370 patients who were treated by Dr Issels shortly after surgery or irradiation shows that 87 per cent were still alive after a period of five years, with no detectable relapse. Dr Issels therefore claims that his treatment reduces the danger of relapse during the first five years to 13 per cent, compared with the world average of 50 per cent.

Whether or not these claims are justified depends to a great extent on the criteria by which Dr Issels selects his patients, and his report does not shed much light on this factor. The report also gives a very sketchy account of his method of treatment, and does not include analysis of control trials. Indeed, Dr Issels has consistently refused, on ethical grounds, to carry out control trials, without which an accurate assessment

of the efficiency of his method for various types of cancer at different stages of development cannot be made.

The treatment given at Dr Issels's Ringberg clinic is a mixture of immunotherapy, chemotherapy and psychotherapy, based on the concept that cancer is a chronic systemic disease. Elimination of the original tumour is carried out by surgery, irradiation, chemotherapy, enzyme therapy and "immunotherapy by both active immunization with mycoplasma vaccine (developed by Dr Gerlach) and passive immunization with antibodies prepared from cancer cells". The most interesting part of the immunotherapy is the use of the Gerlach vaccine, but, unfortunately, few details are given in Dr Issels's article. He says that the vaccine is a mixture of pure cultures of tumour mycoplasmas obtained after ultracentrifugation from tumour tissues of heterogeneous malignant growths. The vaccine is injected intramuscularly or intravenously "for weeks or months in doses depending on the patient's condition". With this sort of vague information to go on, the MRC was right to emphasize that no conclusive evaluation of Dr Issels's methods can yet be made.

POLLUTION

Dangers in Tinned Tuna

AFTER the finding of dangerous concentrations of mercury in tinned tuna fish in the United States, it is not surprising that the laboratory of the Government Chemist has reported similar concentrations in British tins. Although the Ministry of Agriculture has not released the precise results of the preliminary emergency survey of the tinned fish, the nature of the reports suggests that concentrations between 0·3 and 1·0 parts per million—similar to those found in the American fish—have been found. The Government Chemistry Laboratory itself, in its annual report last September, generally allayed the concern about mercury contamination and failed to detect mercury in the total British diet.

In the laboratory's preliminary survey, "a range of mercury levels" was found in samples of tuna, bonito and Ship Jack fish from Japan, Peru, Russia and Yugoslavia. Accordingly, the Ministry of Agriculture and Fisheries warned the public that no assurance could be given that all tinned tuna fish is safe for consumption in quantity over a long period. But "because the consumption a head in this country is only 10 per cent of that in the United States, and in the light of the figures revealed from the small sample examined so far, the problem does not require additional action before more complete information and expert advice has been obtained". This advice will come from the government laboratory after a more extensive examination of fifty species of fish.

This recent wave of concern comes at the end of a year during which the inadequacy of restrictions on the disposal of mercurial residues in industrial wastes have been made painfully clear. In the United States, the widespread contamination of lakes and the high concentrations found in some bird species are causing considerable concern; in Canada, 0·3 p.p.m. have been found in chicken livers and 0·2 p.p.m. have been found in bread. What has also been made clear is that nobody knows what the effects of smaller, sublethal concentrations of mercury are. Whilst it is well known that the metal persists and accumulates in the body, with a multitude of effects ranging from skin rashes to insomnia and loss of memory, very little is known about the long-term effects of concentrations well below the generally accepted safety limit of 0·5 p.p.m. on, for example, phytoplankton, the first link in the food chain. As long as this ignorance persists, safeguards to protect water quality standards will remain inadequate.

NEWCASTLE DISEASE

Live Vaccine Approved

ALMOST nineteen million birds in forty-three counties in Britain are now suffering from fowl pest, and there is little sign that the epidemic has spent its force. Some weeks ago it seemed that the worst was over, but the dismal daily tally of fresh outbreaks has, at last, forced the hand of the Minister of Agriculture—poultry farmers will in future be permitted to use the hitherto illegal live vaccine.

This last ditch attempt to turn the tide of infection follows six weeks of intensive field trials in which the live vaccine was tested for efficacy and safety under close Ministry supervision. The results of these trials indicated that live vaccine—only the strain Hitchener B1 has so far been permitted—may give somewhat better protection to very young birds, and it will have few adverse side effects. No significant side effects were detected when the vaccine was used on 10–14 day old chicks. The chief advantage of the live vaccine lies in its cheapness of manufacture, and the ease with which it can be used to treat poultry *en masse*. Whereas inactivated vaccine has to be administered to each bird individually, the live equivalent can be applied as an aerosol to many birds simultaneously.

It has been suggested that the virulence of the present epidemic, and the necessity to use live vaccine are evidence that Newcastle disease is now endemic in Britain, but this the Ministry have denied. However difficult it may prove to break the hold the disease has, there can be no doubt that the use of live vaccine will have economic repercussions. The veterinary controls which have previously invalidated the use of live vaccine have similarly excluded the import of cheap overseas poultry. When the use of live vaccine becomes general, this ban will no longer apply. The Minister of Agriculture said last week that when the ban is lifted, arrangements would have to be made to safeguard the home market from being undermined by unduly low priced imports.

COUNTRYSIDE COMMISSION

Causes for Dissatisfaction

THE Countryside Commission has good cause for dissatisfaction. It has a staff complement of little more than two-thirds that originally envisaged in the Countryside Act, 1968, and a budget substantially less than the £2 million considered necessary in 1967 for its new powers and responsibilities. And it is also unhappy about the low priority given by the government to landscape values and to conservation in general and in particular, in the national parks and areas of outstanding natural beauty. In its latest annual report (HMSO, 13*s*.) the commission criticizes government

approval of the potash mining activities in the North Yorks Moors National Park, of the scheme for a reservoir at Meldon in the Dartmoor National Park, and of the route of the M40 motorway (London to Oxford) through the Chiltern Hills.

Referring to the potash workings, the commission repeats its concern about the way in which public money could be used to aid private enterprise developments which conflict with the purposes of a national park, and it also questions the national need for three separate companies to exploit so rapidly the potash deposits. The commission's next important battle will be to oppose the building by the Central Electricity Generating Board of a new 1,300 MW power station at Insworke Point near Plymouth, a site which the commission will say at the enquiry next February is a "beautiful and sensitive area of countryside and coast which ought to be conserved and protected from large scale industrial intrusions".

The report also mentions the Arnside–Barrow link road in the north-west of England. This route, chosen by the Ministry of Transport, would run through an area of coast and countryside in the Arnside/Silverdale area which the commission decided in 1967 should be designated an area of outstanding natural beauty. After considering an independent consultant's report on the proposed new road, the commission made history by objecting to the proposal at the public enquiry held earlier this month. It condemned the proposal as misconceived, and claimed that the road would be substandard, create noise and pollution in the countryside and effect only an "absurdly small" saving in time for traffic travelling to Furness from the A6 and M6.

The commission also reports that more than 100,000 visitors called at the Lake District National Park Centre near Windermere during its first full season. And in the Peak District National Park, the traffic management scheme, which was started last July in the Goyt Valley, received almost unanimous approval. Visitors to the valley were persuaded to leave their cars, and were taken into the valley area in minibuses. The success of this scheme may pave the way for similar experiments in other national parks.

CONSERVATION

Balancing the Water Budget

from our Soviet Correspondent

THE Supreme Soviet of the USSR has adopted new legislation governing water usage and water conservation to take effect from September 1, 1971. The law covers all water resources in the Soviet Union—rivers, lakes, reservoirs, inland seas and territorial waters for industrial, agricultural, fishing, transport, power production, fur-producing, cooling, effluent removal, recreational and other purposes. Although the preliminary paragraphs of the law note that state ownership of the water resources of the USSR creates favourable conditions for optimum planning and use, a considerable number of the 46 articles of the law seem to be aimed at resolving the conflicting demands of different sectors of the community. Under the new legislation, all water resources are to be the subject of measures against pollution, blockage and depletion. Although penalties for infringement have not yet been published, special attention is drawn to the possible pollution of reservoirs and lakes by the fouling of their winter ice cover. All existing sources of industrial pollution are to be "liquidated", and no new projects —factories and so on—can be commissioned unless they are equipped with anti-pollution devices.

In addition to pollution, the law also forbids waste and uneconomic use of water, because for some years the availability of the water resources of the USSR have been causing concern. The new law discusses means of government assessment of total and accessible water resources, and emphasizes the need for proper maintenance of a balanced water economy for the basins, economic regions and Union Republics of the USSR. Anti-erosion measures for preserving this balance are especially emphasized and the law also provides for the rapid introduction into the water-budget of any underground reserves which may be brought to light as a result of mining or oil and gas drilling operations.

SEA BED

Exploitation Rights

ALTHOUGH oceans and seas cover some 360 thousand km² of the Earth's surface, with an average depth of about 3,700 m, exploitation of their vast potential is only just beginning. A symposium on the exploration and exploitation of the sea bed and its subsoil, held in Strasbourg earlier this month, was organized by the Council of Europe as a first step towards a possible unified European effort to tap this reservoir of potential wealth.

Although the symposium came to few conclusions, there was valuable discussion of the legal position regarding ownership of the sea bed. The present position is confused, despite the Geneva Convention of 1958 (now ratified by more than 40 countries) covering ownership of the continental shelf. Many countries have already granted licences for oil exploration in areas well out to sea in the oceans bordering their coastlines—this is taken as making *a priori* claims to the ownership of mineral rights in these areas. In Europe, with a large number of countries bordering a small amount of sea, the legal problems are of very great importance, as has been shown by the recent dispute over just which parts of the North Sea should be allocated to West Germany.

But the legal problems still remain largely theoretical for the greater part of the Earth's oceans, and there is urgent need of formal international agreement. Reporting to the symposium, Professor W. H. van Eek suggests that within a few years divers will be able to work usefully down to at least 200 metres, the depth below which even major surface storms have no influence on the local environment.

Discussions are now taking place at the UN about this problem, but national governments in general are very ill informed. A full report of the Council of Europe's symposium will be put before the council's Parliamentary Assembly in January 1971, after which precise recommendations for the establishment and terms of reference of a European Ocean Space Commission and an Institute for Ocean Studies could be made. If this results in a wider understanding of the

problems involved, and produces a common European attitude on how they should be solved, the Council of Europe will have made a major contribution to the future development of world resources.

JOURNALS

Filling a Gap

In line with increasing acceptance of the need for a scientific approach to the management of research and development, the only British journal devoted entirely to the field has recently been published (*R & D Management*, Basil Blackwell). Dr E. A. Davies, formerly Joint Parliamentary Secretary to the Ministry of Technology, says in the foreword that its principal aim should be to promote the " . . . efficient and purposeful management of our R & D whether in government, industry or universities. . . ."

The new journal is edited by Mr Alan Pearson, director of the R & D Research Unit of the Manchester Business School where contacts with industrialists have emphasized the demand for such a journal. He sees it as combining some of the best features of the two principal research management journals in the US. These are *IEEE Transactions on Engineering Management*, which tends to be rather theoretical, and *Research Management*, which has an editorial board of industrialists and errs rather on the side of publishing subjective accounts of individual R & D policies. Mr Pearson says that his journal will attempt to adopt a disciplined academic approach to a topic which must at all times remain both practical and applicable.

These views are also borne out by the activities of the Science Policy Foundation whose aim of promoting the scientific investigation of science itself includes studies of the economics of research and development. The need to ensure that discussion and exchange of information are on an academically sound basis and as free as possible from subjective bias is reflected in the nature of the seminars organized by the SPF. A measure of the interest among middle and top management can be gauged from the attendance of 70 people at the second of a series of five such seminars on the theme "Industrial R & D—sound business or act of faith ?".

The editorial board of *R & D Management* hopes that the circulation of the new journal, published three times per year at a subscription rate of £5, will soon pass the 1,000 mark and that it will be appropriate reading for a wide spectrum of people from directors of research to practising scientists. Its role in the realms of formal education is stressed by Professor F. R. Jevons, head of the Department of Liberal Studies in Science at the University of Manchester and a member of the journal's advisory board. He emphasizes the possible uses of the journal both in joint courses such as those run by his own department and the Manchester Business School and in those optional courses in management economics offered by many engineering schools.

The first issue contains papers on topics such as innovation and the small firm, communication networks in research laboratories and methods for research project selection. It is, however, rather disappointing in its layout, but a rather uninspiring front cover and some blank spaces inside will no doubt disappear as the journal finds its feet.

Parliament in Britain

Open University

The government's plans for the Open University were the subject of several questions last week. But Mr William van Straubenzee, Under Secretary of State for Education and Science, refused to be drawn into making definite commitments. The university's grant for 1971–73 has been assessed for an intake of 25,000 students in the first year, and between 36,000 and 42,000 a year for the next two years, but annual intakes for the following years have not been determined. Asked by Mr Peter Hardy for an assurance that the university will be allowed to make unimpeded progress and will not be used as a cheap form of education for those leaving school at the age of 18, Mr van Straubenzee said that the government's decisions have been announced and will be adhered to. Nevertheless, the government has asked the Open University to look into the possibility of taking students at the age of 18. The government also has no plans for increasing the educational facilities of the Open University. (Oral answers, December 17.)

Post Office Equipment

Asked by Dr Maurice Miller whether the government intends to change the right of the post office to manufacture its own equipment, Mr Christopher Chataway, Minister of Post and Telecommunications, said that he has no proposals to amend present legislation. There has been some speculation recently that the Post Office is considering acquiring some manufacturing facilities of its own. (Written answers, December 14.)

Royal Commission on Environment

Mr Peter Walker, Secretary of State for the Environment, said that he has no intention of reviewing the terms of reference of the Royal Commission for the Environment that was set up by the previous government. Mrs Peggy Fenner said that she was sceptical, however, about delaying tactics like the setting up of Royal Commissions. She asked the minister to bear in mind that what the public wants is not advice, consultation, or coordination, but action. Mr Walker replied that the commission should have freedom to choose which aspects of pollution should be given priority. (Oral answers, December 16.)

Museums Charges

During a debate in the House of Lords on the government's proposal to institute charges for admission to museums and galleries, Lord Eccles, Paymaster General, announced that the grant to the Arts Council will be increased next year by £2·6 million to £11·9 million. Lord Eccles also made it clear that he is entirely in favour of the proposed charges, and that this was not a measure foisted on him by his colleagues. I thought the choice was right, he said, and I asked my colleagues to endorse it. Lord Eccles offered the increase in the grant to the Arts Council as proof of the government's intention of giving more aid to the arts, and he was also considering ways of releasing the publications department of the British Museum from having to return its profits to the government. Despite strong criticism of the government's proposals, members of the House of Lords endorsed them by a vote of 121 to 84. (Debate, Lords, December 16.)

Competition for University Places

A-LEVEL results, viewed as the chief criterion for selecting students for university places, are singularly inefficient. That is one conclusion to be drawn from a report published by the Universities Central Council on Admissions (UCCA, 15*s*). Although that may not be too surprising a conclusion, another fact to emerge from the statistics in the report—that British universities attract a disproportionate number of applicants from the middle classes—is even less of a shock. But the report is, nevertheless, a valuable document. It is the first attempt by the UCCA to analyse in depth the social and academic backgrounds of the students who pass through university selection procedures and the wealth of information which the report provides may serve as useful indicators for higher education planning.

Based on a ten per cent sample of the applicants to British universities for October 1969, the report gives detailed information on the academic qualifications (A-level results, or their equivalent), the social backgrounds, the regional distribution and the subject preferences of aspiring university students. It paints a picture of the many hurdles which lie in the path of such students on their way to a university place, and it gives some indication of the intensity of the competition for university places.

The first fact to emerge from the report is that 64 per cent of the sample of candidates from the UK who achieved at least the minimum entrance qualifications of two A-levels were accepted by the universities in 1969. There were, however, 2,721 applicants in the sample with such qualifications who were rejected. If the sample is representative—and there is little reason to suspect that it is not—some 27,000 people were unsuccessful in the competition for places. Bearing in mind that many of these students eventually found their way into colleges of education and the polytechnics, the so-called pool of untapped ability shrinks to slightly more acceptable proportions, but the output of students from schools with at least two A-levels is expected to more than double during the next ten years. Unless extra places are found, the competition will therefore get even more intense. The report also shows that 46 per cent of the accepted students were given places at their first choice university.

Are the universities, in any case, taking the students with the highest qualifications, in terms of A-level passes? The UCCA report shows that there is a very high acceptance rate for candidates with the best A-level results, but those with average or relatively poor results more or less take pot luck. By scoring A-level results as 5 for a grade *A* down to 1 for a grade *E*, it is clear that those who achieved a score of 9 or more (equivalent to an *A* and a *B* or three grade *C*s) stand a chance of better than 80 per cent of getting into university (see Table 1), but those with lower grades stand an almost even chance of gaining a place. A more revealing analysis, however, is that which shows the ranges of ability of the students accepted for various subjects. There is strong evidence to show that students intending to take arts or social science subjects must achieve higher A-level grades than those intending to take science or technology courses. Of the arts students accepted with three or more A-levels, 85 per cent had scores of 9 or more and 80 per cent of the social science students had similar scores, but of those accepted for science courses, 67 per cent scored 9 or more for three A-levels, and 65 per cent of the technology students had similar scores. But for medicine, only 59 per cent of the students accepted had achieved these results.

Table 1. A-level achievement and university acceptances, 1969

Score on 3 or more A-levels	Accepted	Not accepted	Per cent accepted
15	266	12	93
14	359	26	93
13	406	22	95
12	453	39	92
11	492	49	91
10	488	65	88
9	462	118	80
8	395	150	73
7	267	222	55
6	164	230	42
5	125	199	32
4	90	128	43
3	58	80	42

Evidence of the overwhelmingly middle class backgrounds of university students is given by the finding set out in the report that 31 per cent of the accepted candidates in the sample came from families which belong to the upper economic groups, and only 27 per cent to the lower groups. The percentages of economically active males in the total population in these two groups, however, are 8 per cent and 64 per cent respectively. But the report shows that the bias is not introduced during the university selection procedure, for the number of applications correlate closely with the number of acceptances in each economic group. The universities therefore reflect the middle class bias in the secondary schools.

The suggestion that cost savings in the universities may be made by regionalizing intake—insisting that universities take a large proportion of their students from surrounding areas—is dealt something of a blow by the findings revealed in the report. In regions such as the North-West, London and the West Midlands, which have urban populations large enough for regionalization of intake to be a real possibility, less than half the students accepted in 1969 came from the region in which the universities are situated. Universities in the North-West, for example, accepted only 28 per cent of their students from that region, and similarly West Midlands universities accepted only 20 per cent of their students from surrounding areas. And the situation is even more difficult for universities in East Anglia and the East Midlands—these universities accepted 3·6 per cent and 10 per cent respectively of their students from surrounding areas. More than a third of the sample of students who applied to universities in 1969 came from the South-East, and is seems that the North, East Anglia and the Midlands as a whole supplied less than their fair share of candidates.

NEW WORLD

Tolbutamide Study Raises Blood Pressures

by our Washington Correspondent

DR CHARLES EDWARDS, the new head of the Food and Drug Administration, has stumbled into a controversy that could prove nearly as troublesome to the agency's reputation as was the handling of the cyclamates incident. Two months ago the FDA acted on the basis of a single epidemiological study, still not published in full, to urge that tolbutamide and other antidiabetic agents taken by mouth be used by doctors only on a last resort basis. The sharp dispute that has now erupted within the medical community over the methodology and interpretations of the study has made the action of the FDA look awkwardly premature.

As a result of the FDA's hasty ruling, an atmosphere of suspicion and resentment has been created among diabetologists in addition to their doubts about the validity of the study. Matters came to a head at a recent clinical convention of the American Medical Association in Boston when forty specialists signed a statement on November 30 deploring the FDA's course of action as uncritical, premature and scientifically unacceptable.

The source of the controversy is an ambitious prospective study of tolbutamide that started in 1961 and eventually included some 800 diabetic patients in 12 university centres. The conclusion of the study, reached after 8½ years, is that the tolbutamide therapy, combined with a controlled, low sugar, diet, is no more effective than diet alone in prolonging life. The investigators went on to conclude that tolbutamide and diet may even be less effective than diet alone, or diet and insulin, with respect to the risk of cardiovascular mortality.

Tolbutamide is a chemical that transiently lowers the quantities of sugar in the blood, thus mimicking one of the functions of the natural hormone insulin. It is valued by doctors because unlike insulin it does not have to be injected and can be taken in pill form. Of the 4½ million Americans who suffer from diabetes, about 1½ million have a milder form of the disease which can be treated by oral antidiabetic drugs such as tolbutamide, and about 800,000 use tolbutamide itself (which is marketed as Orinase by the Upjohn Company). The tolbutamide study, a $7 million dollar project financed by the National Institutes of Health and known as the University Group Diabetes Program (UGDP), first came to public attention through press articles in May. The Food and Drug Administration convened an advisory committee on May 20 to advise on its reactions to the UGDP report. The recollection of one of the members is that the committee heard conflicting opinions about the report from three biostatisticians and concluded by saying that the significance of the results needed further discussion. In any event the FDA issued a statement the following day saying that it accepted the UGDP study and would issue a bulletin to doctors later, and order appropriate labelling changes. The bulletin sent out at the beginning of November went rather further than just telling doctors of the UGDP results; it also told them how to treat their diabetic patients. First the patient should be treated by diet and weight control alone, with no other therapy if this is adequate. As a next step insulin should be given, and only as a last resort should the oral hypoglycaemic agents be used.

FDA spokesmen point out that this action has been supported by the American Diabetes Association and the American Medical Association's Council on Drugs. These organizations have indicated their agreement with the stated conclusions of the UGDP study and the AMA group has confirmed the FDA's recommendations on the primacy of diet alone but gives rather more discretion to the doctor in deciding whether to prescribe insulin or an oral diabetic agent as the next step if diet fails. Unfortunately, the sanction of these authoritative bodies has not defused criticism to anything like the same extent as full publication of the UGDP report might have done.

In the first place there have been many criticisms of the methodology of the UGDP study. Although these criticisms may turn out to be groundless or overstated when the full data are published, they are sufficiently important to justify serious reservations in the meantime about the implications of the study and the wisdom of the FDA's action. Defenders of the UGDP survey point out that the final paper has been vetted by no less than six referees and the project as a whole was intensively reviewed at each stage of its eight year existence —but this is not the same as open discussion throughout the usual scientific channels. Perhaps as a result of the relevant facts being unavailable, the air is thick with accusations of bias, chicanery and character assassination.

On top of the reservations about scientific method, there is resentment among the medical community at what is regarded as the FDA's "practising medicine" by specifying how diabetics should be treated, instead of merely passing on to the doctors information about the new results. The statement prepared by doctors at the Boston meeting of the American Medical Association declared the FDA's action an "unprecedented interference with the practice of medicine in a controversial area (which) is not only outside the province of a Government regulatory agency but . . . has also damaged the welfare of a million diabetic patients".

Reception of the FDA's decision has also been made more difficult by the existence of long-standing differences of medical opinion on the management of diabetes. One school of thought, represented by the Joslin Clinic in Boston, where the AMA convention took place, believes in the importance of controlling the level of blood sugar in diabetes. Another view, held by some of those involved in the UGDP survey, is that control of blood sugar level does not have a significant effect on longevity. The results of the UGDP study inci-

dentally tend to favour the latter view, with the result that in the process of confirming the UGDP results on tolbutamide the FDA has seemed to its critics to be cutting across a vexed and as yet unresolved academic controversy.

Dr Robert Bradley of the Joslin Clinic, who helped draft the statement criticizing the FDA, believes along with other doctors that the agency has gone too far in extrapolating the results of the UGDP survey from patients not dependent on insulin, who were the subjects of the survey, to all kinds of diabetics. The agency also seems to have taken a more definite view of the toxicity of tolbutamide than the AMA Council on Drugs felt was justifiable. The council in its statement said only that tolbutamide "*may* have played a 'toxic' role with respect to cardiovascular mortality" but that this interpretation "is quite difficult and may or may not be valid".

Adding to the bad feeling between the agency and the medical community is the series of press leaks, both in this and previous instances, that have alarmed the public and made quick decisions necessary. The AMA at its annual convention in June this year went out of its way to reprove the FDA for its news policies which had "created undue anxiety" among diabetics. According to the November 2 issue of the AMA's newsletter, *American Medical News*, the agency also failed to prepare its bulletin on tolbutamide by the deadline agreed with the AMA and the American Diabetes Association, according to which all three organizations would release statements at the same time. The plan also called for the publication of the full article in October, now not expected until the end of this month.

The fact that the UGDP report is still unpublished seems much to blame for the bickering and backbiting that now surround discussion of the survey and may cling to it for some time to come. Why could the FDA not have waited until the full report was out? "The political pressures are too great to withstand," an FDA official explained last week—"the medical profession always chides the agency as premature when it acts promptly and it is pilloried by Congress and in the press if it bides its time." But if the Food and Drug Administration does not stand up to political pressures in order to allow scientific procedures due process, how is a rational decision to be arrived at? "You must ask Congress that," the official said.

COOPERATION

Brighter Outlook for Astronauts

by our Astronomy Correspondent

ONE of the ways in which 1970 has been a remarkable year is that cooperation between the United States and the Soviet Union in space exploration has at last seemed a possibility, although a remote one. *Nature* has already chronicled the long history of attempts at collaboration (**225**, 1094; 1970) and, whatever the reasons, the tale is depressing. But this autumn, almost out of the blue, moves towards cooperation took place whose outcome so far has, for once, not been disheartening.

Nobody knows what part the near-disaster of Apollo 13 played in the prehistory of the present negotiations with the Soviet Union. But the notion that there could be some kind of standardization of systems allowing Soviet spacecraft to dock with those of NASA and vice versa surfaced at the autumn congress of the International Astronautical Federation (see *Nature*, **228**, 198; 1970). After that the talks progressed remarkably quickly, and the fact that an agreement had been reached between NASA and the Academy of Sciences of the USSR was announced on October 29. On the Soviet side of the talks held in Moscow were B. N. Petrov, K. P. Feoktistov, V. S. Syromyatnikov, V. V. Suslennikov and V. A. Lavrov, and on the American side Robert R. Gilruth, Arnold W. Frutkin, George B. Hardy, Caldwell C. Johnson, and Glynn S. Lunney. Now that the agreement has been confirmed by an exchange of notes between the acting administrator of NASA, Dr George Low, and the president of the Soviet Academy, Academician M. V. Keldysh, the text has been made available.

During the talks, which appear to have been limited to the question of compatibility of rendezvous and docking systems, the two sides exchanged information about their existing methods, and decided on twelve topics which merit further study:

(1) Passive reflectors of the radio guidance systems, their location and characteristics.

(2) Passive reflectors of the optical guidance system, their location and characteristics.

Apollo 14 Timetable

NASA has now published the preliminary timetable for the Apollo 14 mission, which will leave on January 31 for the Fra Mauro formation. All times are in BST.

Event	Date/time (BST)
Launch from Cape Kennedy	Jan. 31, 9.23 p.m.
Leave Earth orbit	Jan. 31, 11.54 p.m.
Leave free-return trajectory	Feb. 2, 3.59 a.m.
Lunar orbit insertion (57 × 170 nautical miles)	Feb. 4, 7.58 a.m.
Descent orbit insertion of docked spacecraft (10 × 58 nautical miles)	Feb. 4, 12.17 p.m.
Lunar module undocks and separates from spacecraft	Feb. 5, 5.47 a.m.
Command/service module moves into circular orbit (56 × 63 nautical miles)	Feb. 5, 7.07 a.m.
Lunar module powered descent to lunar surface	Feb. 5, 10.02 a.m.
Landing at lat. 3° 40′ 19″ S., long. 17° 29′ 46″ W.	Feb. 5, 10.14 a.m.
The two astronauts will stay about 34 hours on the surface.	
Begin 4 to 5 hours of lunar surface activity (EVA)	Feb. 5, 2.50 p.m.
Begin second 4 to 5 hours of lunar surface activity	Feb. 6, 11.30 a.m.
Liftoff of lunar module from Moon	Feb. 6, 7.44 p.m.
Docking with command/service module	Feb. 6, 9.30 p.m.
Lunar module jettisoned on to lunar surface	Feb. 6, 11.43 p.m.
Apollo 14 leaves lunar orbit	Feb. 7, 2.35 a.m.
Splashdown in Pacific Ocean for recovery by USS New Orleans	Feb. 9, 10.01 p.m.

(3) The radio-technical guidance equipment, utilizing active radio signal transmission and return, including its elements, location and characteristics.

(4) Lighting equipment for rendezvous and docking, its elements, relative location and characteristics.

(5) Benchmarks and reference marks for orientation during rendezvous and docking, their location and characteristics.

(6) Coordinate systems for reference in developing rendezvous and docking techniques for spacecraft and space stations.

(7) The docking assembly, inner tunnel and electrical, pneumatic and hydraulic couplings.

(8) Pneumatic, hydraulic and electrical couplings and connectors between space suits and on-board equipment of the spacecraft or stations and their characteristics, the dimensions of hatches and the means of opening them from the outside (in the event that assistance needs to be rendered from the outside).

(9) Composition and characteristics of the cabin atmosphere.

(10) Voice and code communications between spacecraft.

(11) Dynamics of docking and the stabilization of system after docking.

(12) Constraints on the location of thrusters, solar batteries and other design elements which should be borne in mind to assure the possibility of docking.

The agreement goes on to list the next steps to be taken. During November of this year there was to be an exchange of technical details on radio guidance and rendezvous systems, on the composition and characteristics of the spacecraft atmospheres, and the voice communication systems. Then each side is to prepare its own draft of the technical requirements for the systems for which it considers it advisable to ensure compatibility, to be exchanged in January or February next year. This will be followed by a meeting in March or April to discuss and refine the technical requirements that have been put forward, and the agreement allows for an earlier preliminary meeting to prepare the ground. Once agreement has been reached each side, independently, will work out preliminary designs which will then be put to the representatives of each side who will decide what further work is to be done.

Does this mean then that the future Apollo astronauts will enjoy an extra lifeline not available to their predecessors? Unfortunately not. The Apollo programme is almost certainly too unmalleable to make the changes now. The same goes, of course, for the next step by the Americans, the Skylab programme which is still based on Apollo technology. What was being talked about at Moscow then was the compatibility of docking systems in programmes which in the United States have not yet received the go-ahead, the shuttle and the space station. A start has been made nevertheless.

LEAD POISONING

Children at Risk

from our New York Correspondent

LEAD poisoning is one of the most important paediatric problems in New York City according to Dr Vincent F. Guinee, director of the City Health Department's Bureau of Lead Poisoning Control. Speaking at the New York Academy of Sciences last week, Dr Guinee estimated that between 6,000 and 8,000 children in the city have significant levels of lead in their blood. The number of deaths due to lead poisoning has dropped sharply because of improved testing, and is down to two so far this year, but for the same reason the number of known non-fatal cases has risen from 151 in 1959 to nearly 2,500 in 1970.

The chipping paint in older apartments is the primary source of lead poisoning. Paint with a high content of lead was banned in 1959, but Dr Guinee estimated that there are 450,000 apartment units in New York in such bad repair that children could easily eat leaded paint chips. Twelve per cent of the ingested lead is absorbed into the blood, with high enough levels causing irreparable brain damage.

The Bureau of Lead Poisoning has for the past year been seeking out cases, screening more children and attempting to provide preventive care. Dr Guinee hopes that each hospital and clinic will soon automatically include lead-poison screening in its testing facilities. The bureau itself screened more than 79,000 children last year to find the 2,500 with at least 60 micrograms of lead in their blood, the definition of a positive case. The apartments of all positive cases are tested by the bureau; if any painted wall contains more than one per cent lead, the area must be repaired and repainted, either by the landlord or by the bureau at the landlord's expense. Unfortunately, with only 200 workers and a budget of $2·4 million, the bureau cannot begin to test the apartments of those 31,000 children who, when tested, had positive amounts of lead in their blood, not to mention the other 400,000-odd apartments that are probably contaminated.

According to Dr Guinee, the bureau's work during the past year has taught the researchers that (i) results vary greatly according to the depth of the sample; the more children who are screened, the more cases of lead poisoning that will be discovered. (ii) Study in this field has been hampered by semantics—what determines a "case"; where should the cut-off point be? And (iii) there is still a great lack of knowledge—how does a child react to his condition? Is there any psychological damage? Which children can receive treatment and what is a satisfactory or realistic end-point? Also, how is a health hazard measured and how efficiently can the law be enforced?

Lead poisoning is obviously an environmental problem, directly related to deteriorating housing. The obvious answer is to improve the housing, but this takes time and money. Workers in the field see the necessity for enacting stiffer laws and for educating the federal government, but fear that the problem will continue to grow not only as investigation improves, but while more housing is allowed to deteriorate.

But it seems possible that in this field, too, those involved are no longer going to sit back and wait for a change. One of the doctors at the meeting, Dr Rothschild of the Sloan-Kettering Institute for Cancer Research, stated: "What is lacking is that having identified the vector, we throw up our hands and go on treating the symptoms without trying to do anything about the environmental problem that causes it". Dr Rothschild went on to raise the possibility of becoming directly involved in social action. The meeting was receptive to the idea, if not prepared to act on it immediately, a hopeful sign at least for change in the future.

NEWS AND VIEWS

A Prediction Fulfilled

If the only thing more gratifying than having one's predictions confirmed by somebody else's experiments is being able to confirm experimentally one's own predictions, Dr Bernard Davis must be feeling very satisfied. In 1968 he and two colleagues predicted the existence of a factor in *Escherichia coli*, the specific function of which is to cause the two subunits of a ribosome to dissociate. And on pages 1273 and 1269 of this issue of *Nature* he and Dr A. R. Subramanian and Dr S. Ochoa and three colleagues report experiments which prove that dissociating ribosomes of *E. coli* is the function of an initiation factor F_3.

In *E. coli*, the initiation of the translation of a messenger RNA molecule depends on the formation of a complex between the smaller of the two ribosomal subunits, the 30S subunit, a molecule of messenger RNA, and the initiating transfer RNA carrying a formyl-methionine residue (fMet-tRNA$_f$). Only after this initiation complex, as it is called, has been formed can the larger of the two ribosomal subunits, the 50S subunit, associate to yield a 70S ribosome which can then catalyse the formation of peptide bonds and the translation of the entire messenger RNA. Obviously this stepwise initiation process depends on a supply of free 30S and 50S ribosomal subunits, but in 1968 Davis and two colleagues reported that the ribosomes which run off a messenger RNA after translating it completely remain intact as 70S particles. Although there has been something of a dispute about whether or not ribosomes dissociate into their two subunits at the end of each round of protein synthesis, Davis and his colleagues stuck to their guns, maintaining that the dissociation does not occur automatically at the termination of protein synthesis. They therefore postulated that some dissociation factor must exist which functions by complexing with the 70S ribosome, probably to its 30S moiety, and causing it to fall apart into its subunits. And by remaining associated with the 30S subunit the factor would block the spontaneous binding of free 30S and 50S subunits. In other words, the factor would produce and maintain the supply of 30S subunits required for initiation complexes.

Those workers who postulate the existence of factors are behoven to search for and identify the putative molecules, and in 1968 Davis and his colleagues reported that a dissociation factor is indeed solubilized by washing ribosomes with ammonium chloride solutions. But the washings they obtained in this way clearly contained several factors including some which catalyse the steps in the initiation of protein synthesis. Since 1968, several groups have pursued the question of the part various factors play in initiation and three distinct initiation factors, F_1, F_2 and F_3, have been defined and purified.

Davis and his colleagues repeatedly observed that their dissociation factor purified along with the F_3 initiation factor, and now with pure F_3, supplied by Dr Ochoa, they have confirmed that whatever other functions F_3 may have in initiating protein synthesis it is able to dissociate 70S ribosomes into their two subunits. Apparently one molecule of F_3 is able to dissociate one 70S ribosome. Purified initiation factors F_1 and F_2 by contrast have no ribosome dissociation activity and the ability of only partially purified preparations of F_1 to effect dissociation is attributed by Subramanian and Davis to contamination with F_3. They claim that F_3 is the sole dissociation factor, and suggest that each molecule of F_3 remains associated with a 30S ribosomal subunit until it is released during the formation of an initiation complex, whereupon the molecule of F_3 is available to recycle and dissociate another 70S ribosome.

Ochoa and his colleagues, Sabol, Sillero and Iwasaki, have also reached the conclusion that F_3 dissociates ribosomes, but they suggest that this factor may as well function in the formation of the initiation complex. The F_3 which they prepared and supplied to Subramanian and Davis is a basic protein weighing 21,200 Daltons, which can bind to both synthetic and natural messenger RNAs. This binding does not result simply from the basic nature of F_3 because factor F_1 is even more basic, but it fails to bind to the messengers tested. This result led Ochoa and his colleagues to investigate the role F_3 might have in promoting the binding of a 30S ribosome to messenger RNA. They find that both F_3 and F_1 must be present for the formation of a complex between a 30S ribosomal subunit and a messenger RNA. The third initiation factor F_2 is then required for the binding of the initiating fMet-tRNA$_f$ to the ribosome/messenger complex, and after this step has been achieved the 50S subunit can associate and the first peptide bond can be formed. According to Ochoa's group therefore F_3 has a dual function, dissociating 70S ribosomes and promoting the binding of messenger to 30S ribosomes.

Less committed than Davis to the notion that ribosomes running off a messenger remain as intact 70S particles until they meet with a molecule of F_3, Ochoa and his colleagues say that the precise way in which the F_3 factor functions remains an open question. Either as Davis suggests F_3 dissociates from the 30S

ribosome during initiation and then is free to bind to and dissociate a 70S ribosome leaving a messenger, or the F_3 molecules may remain bound, one per 30S subunit, throughout the ribosome cycle. If the latter is the case, ribosomes should dissociate at the termination of a round of protein synthesis; furthermore, the dissociating activity of the factor must be blocked by an aminoacyl or peptidyl-tRNA, otherwise 70S ribosomes would never form. Deciding between these alternatives (and the odds are on the former) will complete the picture of the ribosome cycle in bacterial cells.

REVERSE TRANSCRIPTASES

Roundabouts and Swings

from our Cell Biology Correspondent

On Monday, December 14, Dr Sol Spiegelman, lecturing at the Royal College of Surgeons at the invitation of the Imperial Cancer Research Fund, treated his audience to an adroit review of the prodigious amount of research which he and his colleagues have done on reverse transcriptases in animal cancer viruses and human cancer cells. After briefly discussing the three possible models which account for the replication of RNA viruses in a cellular environment dominated by DNA, and outlining his work on the replication of the phages, Dr Spiegelman reached the meat of his lecture—the significance of the discovery of reverse transcriptases to cancer research and the search for a human RNA leukaemia virus.

The presence of reverse transcriptases in animal tumour viruses makes possible the synthesis of a highly radioactive labelled DNA with a base sequence complementary to that of a tumour virus RNA. If human tumour viruses exist, and if they are related in their base sequences to the animal tumour viruses, such DNA might be an effective probe, in hybridization experiments, for a human tumour virus nucleic acid in a cancer cell. But unfortunately, Spiegelman and his colleagues found in hybridization tests that the base sequences of the various animal tumour viruses are not closely related. This slightly disappointing result means, of course, that there is no good reason to anticipate a close relationship between the base sequences of a putative human tumour virus and any of the animal tumour viruses. DNA complementary to tumour virus RNA is therefore a much blunter probe than everybody hoped it might prove to be.

Synthetic double stranded RNAs and DNAs and RNA/DNA hybrid molecules, on the other hand, have been shown to be more useful than anybody had a right to expect. Certain synthetic nucleic acids are by about two orders of magnitude better templates than any natural nucleic acids so far tested for reverse transcriptases in animal tumour viruses. Armed with this information, Spiegelman *et al.* began to search for polymerase activities, first in the plasma of human leukaemia patients and then in extracts of leukaemia cells. In the cells of more than forty leukaemics, they have now found a polymerase activity which uses poly dT·poly rA as a template, as well as an activity which replicates poly dC·poly dG. This latter activity seems to be present in all proliferating cells irrespective of whether or not they are malignant, but the former activity, which utilizes an RNA/DNA hybrid as a template, seems to be restricted to cancer cells. In addition to being present in leukaemia cells, it has been detected in the cells of two osteosarcomas and one chondrosarcoma. It is interesting, however, that only one of seven Burkitt's lymphoma biopsies, supplied by Dr G. Klein, contained detectable amounts of the poly dT·poly rA polymerase, whereas all contained the activity which replicates poly dC·poly dG.

So far, as Dr Spiegelman took pains to stress, neither his nor anybody else's work on the nucleic acid polymerases in human cancer cells proves the existence of human leukaemia or sarcoma viruses. The polymerase activity which distinguishes human cancer cells from other non-malignant, but proliferating cells, differs markedly from the reverse transcriptase in animal tumour viruses; the two activities can, for example, be differentiated on the basis of their preferences for synthetic templates of various base compositions. But irrespective of any question of the viral aetiology of human cancers, the presence in cancer cells of a polymerase activity which can use a hybrid nucleic acid as a template provides a new tool for diagnosis of cancer and for following the course of remissions and relapses during therapy.

PROTEIN SYNTHESIS

Inside and Outside the Ribosome

from our Nucleic Acids Correspondent

Studies of the structure and assembly of the ribosomal particles from *Escherichia coli* continue to burgeon, and a rich crop is to be found in the November issue of the *Proceedings of the National Academy of Sciences*. Among these articles are the striking results of Chang and Flaks (*Proc. US Nat. Acad. Sci.*, **67**, 1321; 1970) and Craven and Gupta (**67**, 1329; 1970), who have attempted to examine the topography of 30S ribosomal particles by partially digesting them with low concentrations of trypsin or treating them with protein reagents. Chang and Flaks reasoned that if some of the ribosomal proteins are more accessible to the enzyme than others, these will be most rapidly digested. Hence it might be possible to deduce the relative accessibility of the proteins (those which are external and those which are not) in the particle. They therefore analysed the proteins remaining in variously digested ribosomal particles by polyacrylamide gel electrophoresis and compared them with the proteins from undigested controls run in parallel. They report the remarkable finding that those proteins which become associated early with the RNA in the course of the reconstitution scheme for the 30S particles described by Nomura are usually the least sensitive to digestion. Those proteins added at intermediate or late times in the reconstitution are, in contrast, digested more easily. In other words, there is an inverse relationship between the sensibility to digestion of the ribosomal proteins and the order in which they map in the reconstitution of the 30S ribosomal particles. Although there were a few discrepancies and ambiguities, there is, nevertheless, a close agreement to this model considering the relatively unsophisticated method used.

Craven and Gupta report analogous results when the 30S ribosomes are treated with iodoacetate or 2-methoxy-5-nitrotropone (derivatizing —SH and free $-NH_2$ functions respectively). They have also used trypsin insolubilized by attachment to a cellulose matrix, as an agent exclusively restricted to acting at the surface of the particles. This method showed that certain proteins are not attacked by any of these agents, whereas others are consistently accessible to the action of all three. A further class displays intermediate reactivity towards these agents. Once again the accessibility of these proteins is inversely related to their positions in the assembly map.

It is concluded therefore that the proteins which bind to the 16S RNA early in the reconstitution are sheltered within the interior of the 30S ribosomal particle, with the late-binding proteins predominantly towards the outside. This result is a further contradiction of the models of ribosomal structure previously proposed, in which the proteins would be more or less equally accessible to the action of enzymes or chemical reagents, and it reaffirms that the order of assemblage is in part determined by protein–protein interactions.

NUCLEOLI

rRNA Synthesis in *Urechis*

from a Correspondent

THE activities of the fibriller core (which presumably contains the DNA coding for rRNA) and granular cortex of the nucleolus have been extensively and successfully pursued in a wide range of organisms. Cytological studies suggest that RNA is first synthesized in the core and it then moves to the cortex. Biochemical analysis shows that this RNA is the precursor to ribosomal RNA and that this is cleaved and processed to the mature ribosomal particles in the nucleolus. The use of biochemical and cytological techniques in one system has enabled Das *et al.* (*Proc. US Nat. Acad. Sci.*, **67**, 968; 1970) to correlate the labelling of the pre-rRNA components in eggs of *Urechis caupa* with autoradiographs of the nucleoli. The eggs of this marine worm are easily obtained and are free of the follicle cells which interfere with biochemical studies in amphibian eggs. Their slow rate of processing of precursor rRNA makes it easier to follow the fates of all the components. The one very large nucleolus gives good autoradiographs and the rDNA is easily detected in the cores by Feulgen staining. And most important, clean nucleoli can be isolated from the eggs without degradation of the pre-rRNA.

After labelling for 1 to 2 h with ^{3}H-uridine, Das *et al.* found radioactivity in the 38S precursor rRNA (by sucrose gradient centrifugation); silver grains were confined to the nucleolar core. After several hours, the cleaved products of the 38S precursor, the 30S and perhaps 20S precursors to mature rRNA, were labelled, and radioactivity had spread to the cortex. Das *et al.* used actinomycin D to inhibit further RNA synthesis after 2 h labelling and incubation continued for a further 6 h. Then only the 30S and 20S components were labelled and silver grains were confined to the granular cortex. The 38S, 30S and 20S RNA thus methylated after incubation in methyl-labelled methionine. This work probably confirms that the components are ribosomal, but it might be useful to take the experiments further to investigate the processing of the pre-rRNA.

What Das *et al.* did not mention is that the *Urechis* oocyte represents a special case of ribosome synthesis, in which the large size of the nucleolar core seems to be caused by an increased number of ribosomal genes. Dawid and Brown (*Dev. Biol.*, **22**, 1; 1970) have examined the amplification of mitochondrial DNA and of rDNA and have shown that the nucleus of *Urechis* oocytes contains about six times the normal complement of ribosomal genes. Their conclusion is based on hybridization of *Urechis* DNA with *Xenopus* rRNA in non-saturating amounts—not the best of conditions, but their argument seems reasonable. They have shown that *Xenopus* rRNA is about 60 per cent homologous with the rDNA of *Urechis*, fractionated on a caesium chloride gradient, and that the amount of RNA hybridized is proportional to the amount of DNA immobilized on the filters. *Urechis* oocyte DNA hybridized with about three times as much RNA as sperm DNA. Because the oocyte also contains a large excess of mitochondrial DNA, about 60 per cent of the total per cell, it seems that the nuclear DNA contains rDNA amplified at least six-fold.

These results may be compared with those in Amphibia and water beetles, as studied in Birnstiel's and Gall's laboratories. The mature *Urechis* egg contains, according to Dawid and Brown, 12 ng of RNA which is about 3×10^9 ribosomes, some 1,000 times more than in somatic cells. But the rDNA is amplified only six-fold and in one nucleolus, which may be contrasted with the 1,000 or more extra-chromosomal nucleoli, in *Xenopus* oocytes. In both cases sufficient maternal ribosomes are made for early embryonic development, and rRNA synthesis does not need to start again until later in embryogenesis. Thus, amplification of rDNA seems to be associated with extensive synthesis and storage of ribosomes for later use, whether this amplification is in one nucleolus or many. This correlation suggests that the extra chromosomal rDNA may be under different control from the rDNA integrated in the chromosomes of somatic cells. Such a difference would permit oocytes to uncouple the synthesis of ribosomes from protein synthesis, in distinction to somatic cells where these are tightly coupled.

ENZYMES

Spectroscopist's Guide

from our Molecular Biology Correspondent

MANY a sanguine hope has been expressed about the promise of various spectroscopic techniques for determining stereochemical details of interactions at active sites of enzymes, and observing catalytic events. As long as X-ray crystallography remains a static method, they are obviously worth nurturing, even if so far few very memorable results have accrued. Some interesting explorations, using fluorescence, electron spin resonance and nuclear magnetic resonance are to be found in the November issue of the *Proceedings of the National Academy of Sciences.*

Latt, Auld and Vallee (**67**, 1383; 1970) have constructed an excitation transfer system to observe the interaction between carboxypeptidase and its substrates. Three chromophores are involved: tryptophan residues and the cobalt atom (replacing zinc) in the protein, and a dansyl group, attached to a peptide substrate at its N-terminus. The conditions for energy transfer between two chromophores—that the absorption spectrum of the acceptor must overlap with the fluorescence spectrum of the donor—is doubly fulfilled, in that the tryptophan fluorescence overlaps with the dansyl absorption, and the dansyl emission with the cobalt absorption. The enzyme–substrate interaction can then be observed during turnover in a stopped-flow machine by looking at the quenching of the protein tryptophan fluorescence by the bound substrate. In the zinc enzyme this is accompanied by the growth of dansyl emission, which in the cobalt enzyme is wholly or partly extinguished by transfer to the quencher, cobalt. The extent of the latter effect depends on the distance between the dansylated N-terminus of the peptide, and the cobalt, which is close to the C-terminus, where hydrolysis occurs. The extent of transfer depends on the sixth-power of the separation, and from the overlap, and other known parameters, the distance between the cobalt and the dansyl can be calculated, and agrees well with values from model-building for a series of peptides, assuming extended chains. Many such systems could no doubt be devised, and somewhere, some time, if there is any justice, there will be a problem ripe for the plucking.

Another method, which has enormous steric sensitivity, and can be applied to metallo-enzymes, is electron spin resonance. Taylor, Mushak and Coleman (**67**, 1410) have examined the copper and cobalt forms of carbonic anhydrase, also in nature a zinc enzyme. The hyperfine structure of the spectrum reflects the coordination state of the metal, which in the inactive copper enzyme can be deduced to be in the square planar form. The interaction with nitrogenous ligands engenders large changes in the spectrum, from which the degree of covalent character in the binding can be deduced. In the active cobalt enzyme, interpretation of the spectra is more hazardous. The authors suggest that the zinc and cobalt complexes admit of more distortion than the copper, and that this is favourable for ligand exchange. They suggest an equilibrium between square planar and approximately tetrahedral configurations, the latter being involved in the transition states.

Sarma and Kaplan (**67**, 1375) have used nuclear magnetic resonance at 220 MHz to study the interaction of NAD with lactate dehydrogenase. In free solution the co-factor is in the folded, stacked state, as shown by the shifts due to interaction of protons with the currents in the aromatic rings. The barrier for interconversion between the stacked and open forms is low. From the binding constant of NAD with the protein, the proportions of free and bound NAD can be calculated. The spectrum of firmly bound NAD would undergo line-broadening to the point of vanishing, whereas the observed appreciable but not inordinate broadening of all lines can be explained in terms of rapid exchange of bound and unbound co-factor. The ring-current shift is retained on binding, and it is deduced from this and other evidence that the NAD is bound in the folded form. Now this is at odds with the unequivocal crystallographic evidence of Rossmann and his group, as is the statement that nicotine mononucleotide in the presence of AMP does not bind to the enzyme. It seems then that Sarma and Kaplan's hare will not run, in spite of a careful and seemingly convincing analysis of the NMR spectra. One must suppose that they are the victims of an unlucky circumstance (or Murphy's law, as it used to be called), whereby an interaction with an aromatic ring in the protein generates a ring current equal to that arising in the stacked form of the NAD alone. The situation might be further complicated by rapid exchange between the two conformational forms of the enzyme, which, as Rossmann and his colleagues found, interconvert in response to the binding of the adenine ring. The failure of this change in Sarma and Kaplan's conditions would explain both the absence of interaction with nicotinamide mononucleotide and the retention of the stacked conformation in the co-factor. It is even possible that their enzyme (from chicken heart) behaves in a different way from the dogfish enzyme used by Rossmann's group.

ICHTHYOLOGY

Brotulid from the Bahamas

from our Marine Vertebrate Correspondent

THE brotulid fishes present a diversity surprising even to the ichthyologist. They range in size from more than 1 m long to dwarf forms of 50 mm when adult. Most of the 150 or so species that have been described are marine fish, many of them inhabitants of the deep sea; indeed, the deepest known fish from the oceans is a brotulid *Bassogigas* from the Puerto Rico Trench at a depth of nearly 8,000 m (*Nature*, **226**, 501; 1970). It is surprising therefore that other brotulids live in freshwater in the Caribbean region. An interesting new freshwater species, *Lucifuga spelaeotes*, has now been described by Daniel M. Cohen and C. Richard Robins (*Proc. Biol. Soc. Wash.*, **83**, 133; 1970) from a habitat near Nassau in the Bahamas.

Two freshwater species have long been known from caves in the island of Cuba, and Cohen and Robins regard *L. spelaeotes* as congeneric with the two Cuban fishes. Strangely, this group of three species does not seem to be closely related to the Mexican freshwater cave brotulid *Typhliasina*. Cohen and Robins consider that the three species are instead most closely related to the known deep water genus *Cataetyx*, although a moderately close relative, *Calamopteryx*, a small secretive coral reef fish, lives in the tropical West Atlantic. The common ancestor of both *Lucifuga* and *Calamopteryx*, Cohen and Robins conclude, "may await discovery, hidden in the crevices of a tropical Atlantic reef".

The Bahaman species was discovered by Cohen and

Lucifuga spelaeotes, 109 mm long.

Robins in the Mermaid's Pool, a little known limestone sink near Nassau on New Providence Island. This pool is about 75 feet across, with several small openings nearby; the water level is that of the exposed water table. Its salinity is low, about 4·6 parts per thousand. Only two specimens were collected by a diver at a depth of 5 m. The species grows to at least a length of 10·9 cm. Its body is covered with small scales, but the head region is naked. Very large pores on the head open on to a cavernous sensory canal system, and there are well-developed sensory papillae along the sides of the body. The eye is small but relatively well developed and has a lens protruding through an elongate clear window of the outer skin. The fish is thus obviously able to see (in contrast to some of its other cave-dwelling and deep-sea relatives, which are blind), as well as to take full sensory advantage of its near stygian habitat. The colour of the only known specimens is a rich walnut brown, with rather lighter edges to the fins, although Cohen and Robins describe the naked skin in the mucous chambers of the head as an intense white.

The outlook for the continued survival of this fascinating fish can only be described as bleak. New Providence Island is the scene of a booming real estate development, and much of the area surrounding Mermaid's Pool has already been cleared for property development. Even if the pool survives the immediate programme of building (and inland waters have a knack of bringing out the worst in building man), can it survive the almost inevitable pollution which water extraction, sewage effluents, accidental kerosene leakage, and garbage will produce?

MEMBRANES

Transport Systems

from a Correspondent

How cell membranes are organized to perform various specialized functions has been and will continue to be an intriguing problem. That this problem is capable of being solved, however, seems no longer in doubt. This was the generally optimistic view which emerged from a meeting held at the Royal Society on December 10 and 11 to discuss the mechanisms for the active transport of salts and water in living tissues. In the past, progress in this field has depended on the representation of transport processes as simple model systems. An early warning of the dangers of implicit belief in such models was provided by Professor H. H. Ussing (Institute of Biological Chemistry, University of Copenhagen). The critical approach should show that simple models will have only a limited use in explaining how complex tissues operate. Future developments are more likely to arise from an appreciation of how tissues work as a whole, coupled with a detailed knowledge of how transport processes operate at a molecular level.

Nevertheless, the selection for study of epithelia peculiarly suited to perform single functions can still be expected to show how more general processes might work. That such epithelia exist was reinforced through contributions by Professor J. A. Ramsay (Zoology Department, University of Cambridge), on the extraordinary ability of insects to recover water from relatively dry vapour held within the rectum; by Dr K. Zerahn (Institute of Biological Chemistry A, University of Copenhagen), on the peculiarities of potassium transport by the midgut of the American silkworm and by Professor E. J. Denton (Laboratory of the Marine Biological Association, Plymouth) on the possibilities of water and salt transport by epithelia subjected naturally to high hydrostatic pressures.

The association of many epithelia with layers of non-transporting cells has in the past added considerably to the difficulties inherent in studying epithelial transport, but the use of new techniques should lessen these difficulties. Dr D. Erlij (Centro de Investigacion y Estudios Avanzados, Instituto Politecnico Nacional, Mexico DF) described how epithelia could be separated from underlying tissues in the frog skin through the combined use of collagenase and hydrostatic pressure, and Dr M. W. Smith (ARC Institute of Animal Physiology, Cambridge) showed how transport into the intact intestinal epithelium could be studied for periods of time independently from the underlying tissues. In other cases, where there is little opportunity of simplifying the tissue studied, adaptational changes can be used to investigate transport mechanisms. Dr J. Maetz (Groupe de Biologie Marine, Station Zoologique, Villefranche-sur-Mer), for example, spoke about the reversal of sodium transport which takes place in fish gills as they adapt to environments of different salinity. The initiation of membrane changes seems to be induced by changes in blood sodium. Kinetic studies of sodium fluxes in whole fish indicate that new transport sites are being created during adaptation.

A feature of the meeting was the continual reference to the work of Dr J. M. Diamond (Physiology Department, Center for Health Sciences, Los Angeles, California). His original suggestion that intercellular spaces can function as standing-gradient flow systems and that this largely explains the coupling of water to active solute movements is now widely accepted. Clearly, many workers are now re-evaluating their own findings in the light of this still relatively new concept.

STELLAR CLUSTERS

Disruption by Interstellar Clouds

by our Cosmology Correspondent

THE importance of interstellar clouds as disruptive influences on open star clusters has only recently been studied in detail, because of the lack of sophisticated high-speed computers. P. Bouvier and G. Janin have now tackled this problem by numerical experiments, using the CDC 3800 of Geneva University (*Astron. Astrophys.*, **9**, 461; 1970).

Earlier rough analytical work has shown that for interactions occurring at distances comparable with the cloud radii repeated disturbance of a cluster by passing clouds produces a dispersion of its component stars, resulting in the dissolution of the cluster after some 2×10^9 years. Not surprisingly, distant encounters have little effect on the star cluster (compare the results of L. Spitzer, *Astrophys. J.*, **127**, 17; 1970). Like earlier workers, Bouvier and Janin have used the impulsive approximation for the collisions, assuming that the duration of an encounter is much less than the typical periods of stellar motions within the cluster. They have also neglected the tidal influence of the galaxy, so their results can be taken as an upper

limit for the lifetime of these clusters, but their numerical calculations implicitly include the effects of all encounters, ranging from the very distant to close near collisions.

For a cluster containing an initial population of twenty-five stars, the total energy was dissipated over a period of $4{\cdot}5 \times 10^8$ years, as a result of interactions with clouds distributed randomly with a number density of 4×10^{-5} pc^{-3}. In the same period of time, a similar model cluster of twenty-five stars, left to evolve without any interference from interstellar clouds, maintained its original total energy to within 0·1 per cent. The lower value for the cluster lifetime found by this technique shows, when compared with Spitzer's work, that close encounters with interstellar clouds are of great importance in the disruption of open clusters. The process seems therefore to be similar to the evaporation process, where a large number of distant interactions cannot give an individual star sufficient energy to escape from a cluster, but close encounters with other stars can give it a net positive energy.

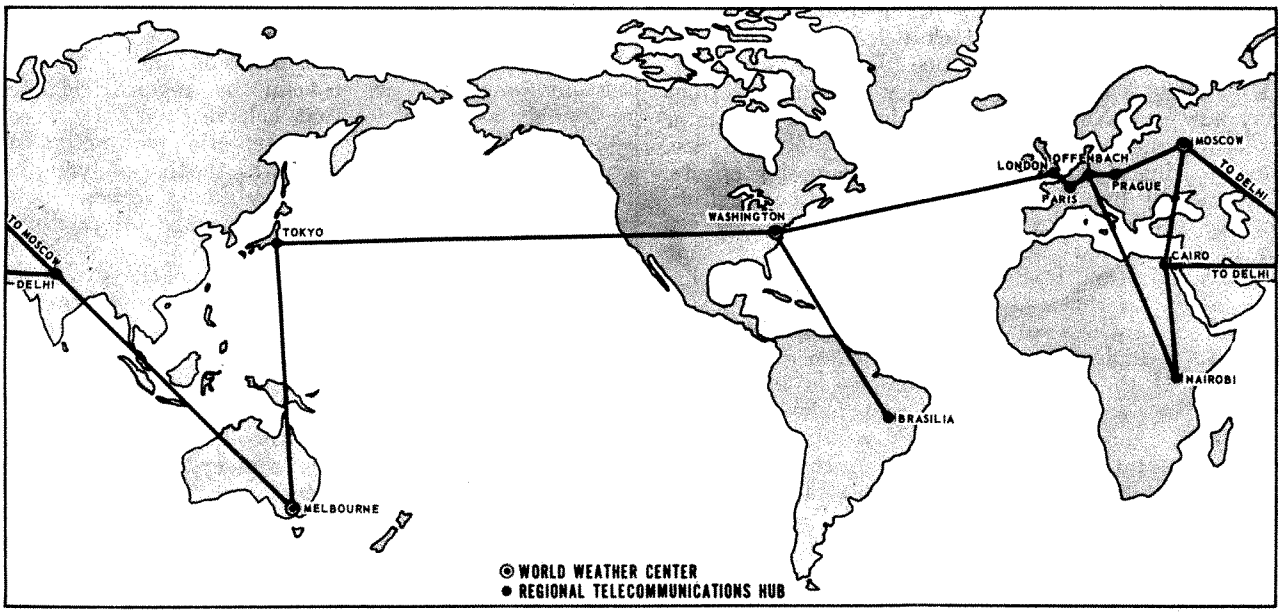
METEOROLOGY

Hot Line to Weather

from our Geomagnetism Correspondent

HOT lines, hitherto restricted to politicians anxious to avoid the hazards of instant war, are now to be used to combat another potential source of catastrophe —the weather. In any period of 24 hours, more than 100,000 observations of weather conditions at the Earth's surface and more than 11,000 observations of the upper atmosphere are recorded at about 8,000 land stations scattered throughout the world, aboard 4,000 merchant ships and on 3,000 transport and reconnaissance aircraft. The transmission of this growing quantity of data to a central point for the preparation of six-hourly weather charts presents a formidable problem of information exchange. Present communications systems are in danger of being swamped.

To come to terms with this problem, the World Meteorological Organization, an agency of the United Nations, set about planning the World Weather Watch in 1967. The first phase of the new global telecommunications system, a hot line between Washington and Tokyo which transmits information at the rate of 3,000 five-character words a minute, came into use last week. If all goes according to plan, the high-speed network will be extended to other major world cities during the next five years, though in most cases this will just mean speeding up existing links. Among the expected benefits of the new system is longer range forecasting.



TEKTITES

Australite Analyses

from our Geomagnetism Correspondent

THE origin of tektites is as obscure as ever. So, in the meantime, work continues on individual samples and groups of samples in an attempt to determine how many different tektite falls there have been and how many different mineralogical types exist. The ultimate hope is that from detailed chemical comparisons some unifying property will emerge to permit an unambiguous interpretation of tektite origin.

That many more hard data are required before even simple relationships can be defined properly is evident from, for example, the problems which have arisen in connexion with the Australian tektite field. The microtektites found in deep sea sediments close to the tektite strewn fields of Australasia and the Ivory Coast apparently fall into two distinct chemical groups—the so-called "bottle green microtektites" which have low silica and high magnesium contents, and the so-called "normal microtektites", the chemistry of which is very similar to that of the Australasian tektites, especially in that the silica contents are high. It is debatable, however, whether there really are two distinct types of microtektite. It is sufficient to say that the range of microtektite compositions is apparently wider than the range of tektite compositions.

Proposed high-speed global telecommunications system forming the World Weather Watch.

In particular, there is a lack of reports of high magnesium tektites, the continental equivalent of the deep sea bottle green microtektites.

This lack of symmetry has led some people to question the identification of the Australasian microtektites. Other workers, on the other hand, believe that the absence of high magnesium tektites is more apparent than real, the problem being merely one of unrepresentative sampling. Moreover, and for a similar reason, the compositional range of even the normal tektites may not be as restricted as it has hitherto appeared. Glass, for example, has been carrying out detailed electron microprobe analyses of a single flanged australite (Australian tektite) and has found a remarkably wide range of composition within the one sample (*Earth Planet. Sci. Lett.*, **9**, 240; 1970). In particular, the silica content varies from 59 per cent to 85 per cent, which easily encompasses the 59 per cent to 76 per cent range of previously analysed normal microtektites. Furthermore, it compares with the previously reported range of 69 per cent to 79 per cent silica for twenty-three australite analyses. The point is that if a single australite can vary to this extent, similar analyses of other australites could easily result in a wider silica range which would encompass all microtektites whether normal or bottle green.

Thus, contrary to the impression given by previous limited data, Australasian tektites probably have a wide range of compositions. If this is the case, there is then no reason why the tektites and adjacent microtektites should not have had a common origin. Such a conclusion has always had strong circumstantial support but it has, until now, seemed to contradict the evidence from detailed analyses.

LIQUIDS

New Light on Solutions

from our Statistical Mechanics Correspondent

WHAT exactly happens when two liquids "mix" or when a solid is "soluble" in a liquid? This may be one of the oldest problems of physical chemistry but perhaps it is beginning to crack at last; some preliminary studies by Weres and Rice (*J. Chem. Phys.*, **52**, 4475; 1970) suggest that a theory of liquid solutions may now be possible. In solid solutions the atoms or molecules involved are usually about the same size, thus creating a balance between two opposing effects. Energetically like atoms usually prefer to be together. On the other hand, "mixed-up" configurations are far more numerous than "segregated" ones, so that thermal agitation tends to cause mixing of unlike molecules. In thermodynamic language, "there is a gain of entropy as a result of mixing" and, if the temperature is high enough, this can balance a loss of energy. If there were no difference in interaction energies between pairs of like and pairs of unlike molecules, "good" solubility could result (miscibility in all proportions), for the same reason that a mixture of red and blue grains of sand assumes a uniform colour when well stirred up.

This problem, of following qualitatively the balance between energy and entropy in a solid solution, has been studied, with various degrees of mathematical subtlety, since about 1930 a very important landmark being Onsager's famous *Physical Review* paper of 1944. Paradoxically therefore solid solutions are better understood than liquid solutions. One solid can be dispersed in another without, in many cases, any significant change of lattice structure, but this is probably never true of liquid solutions.

In a liquid, the interchange, by thermal agitation, of a pair of unlike molecules changes not only the energy and entropy, but also the immediate surroundings of both of these molecules. A liquid does not possess an actual lattice structure, but a "distribution function" can be defined that describes the average surroundings of a typical molecule. This function can be determined by X-ray and neutron scattering and, since about 1960, there have been theories for calculating it with reasonable accuracy. What still has to be allowed for, in discussing the solution process, is that the immediate surroundings of a large molecule may be very different from those of a small one.

Much theoretical work has been done on mixtures of non-attracting rigid spheres of different sizes, partly analytical, partly based on the use of large computers. Not surprisingly, theory predicts that, without interactions, there should be miscibility in all proportions. It should now be possible to put together a theory that balances the rather subtle geometric effects against the direct effects of intermolecular interaction and thermal agitation.

In some well known work in 1967, Barker and Henderson (*J. Chem. Phys.*, **47**, 2856 and 4714; 1967) showed that, if the properties of a (fictitious) assembly of hard non-interacting spheres are regarded as known, it is possible to devise a perturbation procedure that allows for the "softness" of real molecules and for the fact that, at large distances, they attract one another. This approach has been followed up by various other workers with very promising results. (It is obviously better to take the "rigid sphere fluid" as a starting point than to begin, as older theories did, with a solid or gas-like structure.) Many details remain to be worked out, but it is clear that this approach has come to stay. More recently, Weres and Rice have reported work on a perturbation treatment of liquid mixtures, starting from the now fairly well known properties of mixtures of non-attracting rigid spheres of two sizes. They studied the mixtures hydrogen–argon and methane–tetrafluoromethane which can be regarded fairly reasonably as molecules that behave as if they were spherical. After adjusting the interaction parameters to give the best possible agreement with the thermodynamic properties of the substances, they used a rather rough and ready procedure for estimating the interactions between unlike molecules and then attempted to calculate the thermodynamic properties of the mixtures. The agreement with experiment is reasonable for hydrogen–argon, less good for methane–tetrafluoromethane.

As always in this type of work, it is difficult to separate out the effects of the approximations used from the effects of our imperfect knowledge of the interactions. Nevertheless, the preliminary results of Weres and Rice suggest that recent work on mixtures of rigid spheres may be a satisfactory starting point for a theory of liquid solutions. As always, there are nagging doubts about the best way to set up a perturbation treatment, the rapidity of its convergence and the like, but these will not deter the enthusiast.

Wordsworth and Hamilton

by
GEORGE DODD
42, Haygarth,
Knebworth, Hertfordshire

The 200th anniversary of Wordsworth's birth seems to be a good time to recall one of the most interesting and best documented associations between an outstanding poet and a major scientist. The Irish mathematician Hamilton and the English poet Wordsworth were friends and correspondents for more than twenty years. Each helped to mould the ideas of the other significantly.

It comes as a surprise to most scientists to think of Wordsworth—the leader of the romantic poets—as having an interest in and expressing opinions on scientific matters. That he did so was largely due to his friendship in his later years with the Irish mathematical-physicist William Rowan Hamilton. The bond which first brought them together and held their active interest in a correspondence lasting more than twenty years was Hamilton's poetry. From his early youth and concurrently with his mathematics, Hamilton had been a prolific poet. For several years (1822–1829) the young Hamilton could not decide whether to abandon mathematics for poetry and wondered whether he had a true instinct for poetry. What was more natural for the young mathematician, distinguished at so early an age, than to seek the advice of the current doyen of English poetry. Wordsworth in his later years spent considerable effort in advising would-be young poets. He took a particular interest in the young Hamilton and from this grew a deep mutual respect. Later Wordsworth was to say that the only two people in whose presence he felt inferior were Coleridge and Hamilton.

Hamilton was born in Dublin in 1805 (ref. 1). His father, a solicitor, had defended the outlawed Irish patriot Archibald Hamilton Rowan and had obtained a reversal of his sentence. From Rowan, who acted as sponsor at the baptism of the infant William, the boy received his second Christian name. His early development is well known. He was at three a superior reader of English and was considerably advanced in arithmetic. At five, besides being a good geographer, he was able to read and translate Latin, Greek and Hebrew and he loved to recite long passages from Dryden, Milton and Homer. And so he continued until at the age of thirteen he could speak a language for every year that he had lived. Mathematics was not neglected, however, and in his seventeenth year, while heavily engaged in classical studies for university entrance, he records that he was also reading the works of Newton, Lagrange and Laplace. He discovered a mistake in the reasoning in the *Mécanique Céleste* of Laplace and brought it to the attention of Brinkley, the Astronomer Royal of Ireland. The first sign of his creative ability came in a letter to his sister Eliza in the same year, in which he spoke of "some curious discoveries". These were the essentials of what he developed in the next five years into his *Theory of Systems of Rays*. In it he explicitly recognized that optics and dynamics are essentially a single mathematical subject. His plan was to characterize or describe any optical or dynamical system by means of a single mathematical function and has led to one of his enduring memories, the familiar Hamiltonian functions of classical and quantum mechanics[2,3].

The year of Hamilton's birth, 1805, was also a landmark in Wordsworth's life[4]. The poet was in his thirty-fifth year and had been married for three years. In this year his brother John was drowned. This family tragedy moved him deeply and turned his thoughts towards more spiritual things. There began a more mature and less hectic phase of his poetry. The earlier, bolder, Wordsworth who lived in revolutionary France during 1791–92 (and who returned to England in 1792 leaving behind a daughter who had been born out of wedlock) matured into a sober middle-aged Anglican poet. The synergistic creativity of Wordsworth and Coleridge which produced *The Lyrical Ballads* in 1798 and began the romantic movement in poetry was over by 1805 (ref. 5).

From 1802 to 1822 Wordsworth wrote most of his major mature works including "The Excursion", "The Immortality Ode", "The White Doe" and "The Prelude" (which was not published in his lifetime). During this period Hamilton had come of age, intellectually, and had entered Trinity College, Dublin, at the end of 1823 to begin a career that was brilliant in both classical studies and mathematical research. His letters show that he first began to write poetry at the age of fourteen. The visit of King George IV to Dublin in 1821 excited the young Hamilton and he began to produce his first mature verse. At Trinity College his prizes for science and classics were complemented by prizes for his verse. The last year of Hamilton's undergraduate studies, 1827, is an important landmark both for his mathematical research and for his relationship with Wordsworth. Newton had died exactly one hundred years earlier in 1727. In the ensuing century the initiative in mathematics was taken by the continental schools[6] and the imposing edifice of classical mechanics was erected, notably by Lagrange and Laplace. This phase ended with the death of Laplace in 1827. Hamilton, while still an undergraduate, consciously tried to continue and extend Lagrangian dynamics. In 1827, before he graduated, he had brought his youthful discoveries to fruition and in April of the same year he presented his *Theories of Systems of Rays* before the Royal Irish Academy[7]. Later in the same year, though still an undergraduate, he was elected as Professor of Astronomy and Astronomer Royal of Ireland, over the heads of established English astronomers.

Hamilton was always supremely confident of his mathematical ability. He was, however, unsure of his poetic ability and took steps to gain a critical appraisal in 1827. Following the excitement of his election as professor of astronomy in June, he went on an extensive tour of Ireland and England culminating in a visit to the Lakes and Wordsworth in September[8]. A deep rapport was instantly established between the two men. In after years Wordsworth referred with pleasure to their first meeting. Hamilton and his friends had tea and spent the evening with the Wordsworths at Rydal. Wordsworth walked back with his guests to their lodgings about a mile away near Ambleside. Here, such an interesting conversation had developed that Hamilton decided to accompany Wordsworth back to Rydal. On arrival there Wordsworth decided they could not break off the conversation and so

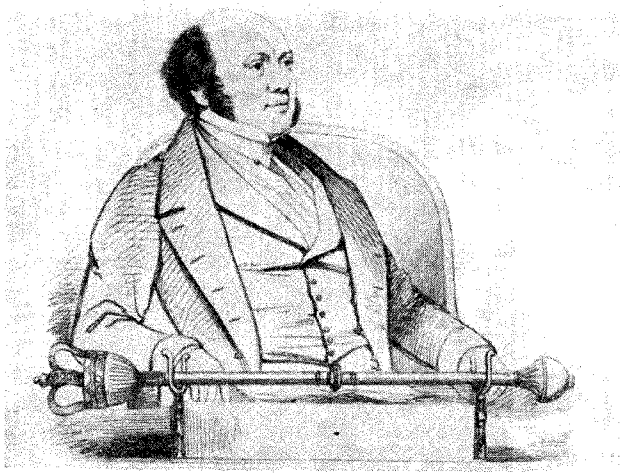


Fig. 1. W. R. Hamilton.

they turned around and walked back to Hamilton's lodgings, where once again they turned and walked back to Rydal, Hamilton returning at a very late hour. His meeting with the poet inspired him to compose a poem "It Haunts me Yet" which he sent to Wordsworth for approval[9]. In reply Wordsworth wrote "You will have no pain to suffer from my sincerity. With a safe conscience I can assure you that, in my judgement, your verses are animated with true poetic spirit, as they are evidently the product of strong feeling,...you will not, I am sure, be hurt, when I tell you that the workmanship (what else could be expected from so young a writer ?) is not what it ought to be.

> "Some Touch of human sympathy find way
> And whisper that while Truth's and Science's Ray
> With such serene effulgence o'er thee shone"

Sympathy might whisper, but a Touch of sympathy could not. "Truth's and Science's Ray for the ray of Truth and Science is not only extremely harsh, but a ray shone is, if not absolutely a pleonasm, a great awkwardness; a ray fell or shot may be said, and a sun, or a moon or a candle shone, but not a ray."

Similar comments were made on some other parts of the poem. Hamilton made a spirited reply justifying his choice of certain terms but still felt unsure of himself as a poet. He concluded: "I am, I assure you, sincerely conscious of the general defects of my poetry and deeply feel the little likelihood that there is of one so devoted to Science as myself ever attaining a high place in the ranks of poetical composition".

In 1829, at Hamilton's suggestion, Wordsworth fulfilled a long-cherished desire by visiting Ireland[10]. Unhappily Ireland was then, as now, in a "rioting time" and Wordsworth wondered if it was safe to come but was reassured by Hamilton. In spite of home sickness and anxiety for his family, the tour was one of the most energetic made by Wordsworth. Of his tour in the county Kerry he wrote: "We left Kenmare each on a vile Irish hack horse at five in the morning...Rode 11 Irish miles (about 15 English). Took to our feet, clomb and clomb till we reached the summit of a ridge, descended,...Took the mountain of Carranthouel, the highest in Ireland,—having taken nothing all day but a bad breakfast—one crust of bread and two basins of milk and a glass of whiskey"[4].

The tour began with Wordsworth visiting Hamilton and his family. Hamilton's sister Eliza has left a detailed account of the visit[10]. When the ladies entered the drawing room before dinner they found Wordsworth reading some of "The Excursion" aloud to his host. "The poet hastily turned round, with a gesture of politeness, moving his face, and indeed his whole body, in the direction to which we passed." The passage which he had been reading had displeased Hamilton by what appeared to be its "slight reverence for science". It was evidently those lines in the fourth book[11] in which the wanderer criticizes the "presumption" of men of science who "pry" and "pore".

> "Viewing all objects unremittingly
> In disconnection dead and spiritless;
> And still dividing, and dividing still,
> Break down all grandeur, still unsatisfied
> With the perverse attempt, while littleness
> May yet become more little; waging thus
> An impious warfare with the very life
> Of our own souls! . . . .
> Philosophers, who, though the human soul
> Be of a thousand faculties composed,
> And twice ten thousand interests, do yet prize
> This soul, and the transcendent universe
> No more than as a mirror that reflects
> To proud self-love her own intelligence;
> That one poor finite object, in the abyss
> Of infinite Being, twinkling restlessly!"

This attitude which Wordsworth had maintained ever since these lines were written in 1798 he now had to defend in the presence of a scientist.

"Wordsworth", says Miss Hamilton, "first finished the passage, in a very low impressive tone, moving his finger under every line as he went along, and seeming as he read to be quite rapt out of this world. He then defended himself, with a beautiful mixture of warmth and temperateness, from the accusation of any want of reverence for science, in the proper sense of the word—on the contrary he venerated it 'when legitimately pursued for the elevation of the mind to God'. But science as the mere accumulation of facts, and above all science which waged war with and wished to extinguish imagination in the mind of man was worse than useless. He would rather be a superstitious old woman than have his mind engrossed with knowledge that was merely material in its aims and uses. As for Newton, and men of science such as he, to whom he paid no tribute in "The Excursion"—" 'What', he said, 'would have been the use of my praising such men as Newton ? They do not need my insignificant praise, and therefore I do not allude to such sons of science'." Yet not very long after his discussion with Hamilton, he made to Newton the most famous allusion ever made to a scientist. In the third book of "The Prelude" he had spoken of the statue of Newton in the chapel of Trinity College, Cambridge

> " . . . Newton, with his prism and silent Face"

When, early in 1832, he began his great revision and correction of "The Prelude" texts, he added to this line two more

> "The marble index of a mind for ever
> Voyaging through strange seas of thought, alone."

Whatever had been lacking before in tribute to Newton was now supplied in marvellous perfection. It is likely that the memory of that evening in Dublin with Hamilton played its part in his decision to make the change.

An immediate effect of the visit was that Wordsworth managed to persuade Hamilton that poetry absorbed the whole man and that he must renounce the hope of habitually cultivating both poetry and science. Characteristically, Hamilton's decision was made concrete in a poem "To Poetry" which concludes

> "Spirit of Beauty, though my life be now
> Bound to thy sister Truth by solemn vow;
> Though I must seem to leave thy sacred hill,
> Yet be thine inward influence with me still;
> And with a constant hope enquire,
> And with a never quenched desire
> To see the glory of your joint abode,
> The home and birthplace, by the throne of God."

In spite of his good intentions, Hamilton continued to produce poetry, some of which was submitted for criticism to Wordsworth. From time to time Wordsworth further urged him not to get engrossed in poetry to the detriment of his mathematics. Two years later Wordsworth writes "You send me showers of verse, which I receive with much pleasure, as do we all yet have we fears that this employment may seduce you from the path of Science which you seem destined to tread with so much honor to yourself and profit to others".

In the early 1830s Hamilton made important advances in his optical and dynamical researches. Although the two basic principles of least time in optics and least action in dynamics had been known for many years, he was the first to appreciate that there is a close mathematical analogy between the path described by a ray of light in a medium and the path described by a material particle in a field of force[12]. He quickly realized that the methods which he had discovered earlier in optics could be extended to dynamics[3,13]. This application of his methods culminated in his famous paper in the *Philosophical Transactions of the Royal Society* in 1834—"Essays On A General Method in Dynamics"[14]—in which the methods of what is now called Hamiltonian mechanics were outlined. This work attracted a good deal of attention and in 1835, on the occasion of the meeting of the British Association for the Advancement of Science in Dublin, he was knighted at the age of thirty. For Wordsworth it was a case of "Whether Sir William or plain Mr. Hamilton be you assured of my affectionate admiration". The friendship between the Hamilton and Wordsworth families was further cemented by Hamilton becoming, at Wordsworth's request, a godfather to one of his grandchildren.

In their correspondence, Wordsworth was interested, as a layman, in scientific matters but regretted his lack of knowledge. In a letter thanking Hamilton for a gft of his "Introductory Lectures on Astronomy" he said: "Your lectures I have read with much pleasure. It is philosophical and eloquent and instructive and makes me regret, as I have had a thousand occasions of doing, that I did not apply to Mathematics in my youth. It is now, and has long been, too late to make up for the deficiency". Wordsworth was critical about the behaviour of some of his contemporary scientists. Just before the meeting of the British Association in 1833 he wrote to Hamilton: "I hope that in the meeting about to take place in Cambridge there will be less of mutual flattery among the men of Science than appeared in that of the last year in Oxford. Men of Science in England seem inclined to copy their fellows in France, by stopping too much out of their way for titles and baubles of that kind, and for offices of state and political struggles which they would do better to keep out of".

When Hamilton became a friend of Wordsworth, it was inevitable that in time he would meet Coleridge. Coleridge's poetry had flourished in the six years when he was in constant contact with Wordsworth (1797–1803). When Hamilton came to know him in 1832, two years before the poet's death, it was in the time of Coleridge the philosopher and theologian rather than the poet. Hamilton, like Coleridge, was fond of metaphysical speculations. His metaphysical thinking and reading provided the intellectual framework which led to his conceptual breakthroughs in dynamics and algebra[15]. Wordsworth provided Hamilton with an introduction to Coleridge and he paid a visit to the ailing philosopher, in London in 1832. This led to an interesting correspondence on the philosophical notions of matter and atoms. From it we learn that Hamilton, like his contemporary Faraday, was influenced by Boscovichean atomism[16]. Wordsworth was delighted that his two great friends had met each other and had philosophical ideas in common.

For both Hamilton and Wordsworth 1843 was a particularly important year. Wordsworth was appointed poet laureate in April. In a letter to Hamilton he relates how initially he refused the flattering invitation on the grounds of his advanced age but that eventually, as a result of the urgings of the Lord Chamberlain and Sir Robert Peel, he accepted. For Hamilton it was the year in which he discovered quaternions[17,18]. During the previous fifteen years he had been studying problems in the algebra of imaginary numbers. How, he wondered, can imaginary numbers, which can be represented in the plane by the Argand diagram, be generalized and represented in space[19]. The answer, which came to him literally in a blinding flash, was that although a two term expression sufficed for the Argand diagram, a four term expression—a quaternion, and not a three term expression as had been commonly supposed—was necessary for the three dimensional situation. It was also necessary to do what was then virtually unthinkable, to violate a familiar algebraic operation and introduce the notion of non-commutative multiplication[20]. These novel concepts were seminal for the development of linear transformations, matrices, and vector analysis by the British mathematical schools of the nineteenth century.

From this year to Wordsworth's death in 1850 there was less contact but no diminution in affection between the two. Hamilton threw his immense energy into the exploitation of quaternions and still found time to write poetry. The ageing Wordsworth, who found it increasingly difficult to read and write, spent his time agitating about the incursion of the railroad into the lakes, besides his official duties of laureateship and the more pleasant duty of playing the grand host at Rydal[4]. Hamilton paid his last visit to Wordsworth in 1844 (ref. 4). On a hot July day, they walked, with mutual friends, to Loughrigg Tarn. The familiar scene stimulated Wordsworth to write a happy little poem in a new form of verse—triple measure.

Wordsworth's death in 1850 deeply grieved Hamilton. He thought of those "personal visits which are among my brightest and fondest recollections". Fittingly, some time afterwards, he commemorated the passing of his friend and mentor in a religious poem "To An Afflicted Friend".

Transfer RNA Methylases and Cancer

by

VALDA M. CRADDOCK

Biochemical Mechanisms Section,
Toxicology Unit,
MRC Laboratories,
Carshalton, Surrey

There is much evidence to suggest that tRNA methylases in tumours differ from the enzymes in normal tissues. The experimental basis and possible significance of the changes in activity and in specificity of these enzymes are discussed in this article.

ABOUT ten years ago the rather unexpected discovery was made of a group of enzymes which methylate nucleic acids at the polynucleotide level. It had been known for some time that small amounts of methylated bases were present in RNA from various sources[1,2], but it had been tentatively assumed that this could be explained by incorporation of the bases during nucleic acid synthesis, rather than by modification at the macromolecular level. This assumption was proved wrong during work on a methionine auxotroph of *Escherichia coli*.

Most amino-acid auxotrophs synthesize RNA only when the amino-acid is supplied in the medium; if it is not, synthesis of both protein and RNA is inhibited. But although the *E. coli* in question was unable to synthesize methionine and so required an external supply for growth, it continued to synthesize RNA in the absence of the amino-acid. The RNA formed in these conditions was deficient in methylated bases[3] but became methylated when methionine was added to the incubation medium[4]. The enzymes responsible, the nucleic acid methylases, have since been found in almost every type of cell system investigated. The function of this universal methylation of tRNA remains obscure, however. Because current concepts had no obvious need for tRNA to be methylated in order to carry out its functions in protein synthesis, it was suggested that methylation was involved in the control of protein synthesis at the level of translation. In determining what type of protein is made it would thus determine the type of cell formed and so control differentiation. Thus, as cancer can be considered to be a disease of differentiation, involving essentially a change in cell type, it was conceivable that changes in tRNA might be responsible for carcinogenesis. The alterations in tRNA which have been studied most in relation to carcinogenesis have been changes in methylation.

Simultaneous with the proposal that changes in tRNA methylases might be involved in carcinogenesis, a different line of work led to the suggestion that methylation of nucleic acids was significant in the action of chemical carcinogens. This work began when it was found that administration of the carcinogen dimethylnitrosamine to the intact animal led to the methylation of liver and kidney DNA and RNA[5]. Methylation occurred chiefly on the N^7-position of guanine. Dimethylnitrosamine is metabolized in liver and kidney to form an alkylating intermediate. Other nitrosamines, nitrosamides, and N-methyl-N-nitroso-N′-nitro-guanidine act as carcinogens for different organs, and in each case where alkylation of nucleic acids has been studied, with a few possible exceptions, it has been shown to occur in organs which would have developed a tumour if the animal had been kept alive[6]. Thus there was debate as to whether cancer could be due to alkylation of RNA or of DNA.

When the nucleic acid methylases were discovered it seemed possible that certain carcinogens, such as nitrosamines and nitrosamides, might act by causing direct alkylation of nucleic acids, while others, which could not act as alkylating agents themselves, might bring about a similar end result by causing an increase in activity or an aberrant activity of the methylase enzymes. For these reasons, investigations of nucleic acid methylases in relation to cancer began in several laboratories. Evidence was found for an increase in activity and a change in specificity of the enzymes in various tumours. The sequence of events which brings about these changes is not known, and the exact nature of the changes is not understood. But, perhaps most important in the present context, it is not known whether the changes observed are an essential part of carcinogenesis, or whether they are coincidental to the malignant process.

Properties of tRNA Methylases

tRNA methylases are probably located in the nucleus of the cell[7], the tRNA being methylated as it is synthesized and before it passes into the cytoplasm. The tRNA methylases alkylate each of the four major bases and also the 2′ position of the ribose moiety[8]. Although the enzymes responsible for methylation of the sugar have not yet been studied in relation to carcinogenesis, base methylation has been studied in some detail. Only certain methylated bases are formed and these differ according to the source of the tRNA. For example, the major methylated bases in rat liver tRNA are 5-methyluracil, 5-methylcytosine, 7-methylguanine, 1-methylguanine, N^2-methylguanine, N^2-dimethylguanine and 1-methyladenine[9]. tRNAs of HeLa and L cells contain the same methylated bases but in slightly different proportions[10], while tRNA of *E. coli* contains 2-methyladenine and N^6-methyladenine also[11].

Sequence studies have shown that methylation occurs only at specific sites in the tRNA of each amino-acid and for each cell type studied. Two examples are given in Fig. 1. As a result of this specificity, methylases from one species can methylate tRNA from that species to a certain level only, and a saturation point is reached. A methylase preparation from another species can bring about further methylation until a new saturation level is attained[12]. Thus it was clear why such highly active enzymes had escaped detection. In normal conditions, tRNA as isolated as fully methylated by its homologous enzymes as is compatible with their specificities. Incubation with enzymes from the same source would not methylate tRNA, as the sites for methylation would have been alkylated *in vivo*. But because the enzymes are species specific, incubation of tRNA from one species with enzymes from another species can lead to "unnatural" hypermethylation. Thus it is possible

to assay mammalian enzymes by incubation with tRNA from bacteria, and this is what has been done in most studies on tumour tissue. It is important to remember in assessing the results of this work that the enzymes are not acting on their normal substrates.

Altered Methylation and Cancer

If tRNA is normally fully methylated by its homologous enzymes as it is synthesized, it is difficult to see how an increase in activity of the methylase enzymes could have any effect on the level of methylation reached in the intact animal. There are, however, two ways in which the pattern of methylation could be changed. There could be a change in specificity of some or all of the methylase enzymes, so that their action on normal pre-methylated tRNA would bring about methylation of bases at sites not normally methylated. Alternatively, there could be a change at the level of transcription of tRNA, resulting in an altered base sequence. Then normal methylase enzymes acting on an altered substrate would bring about a different pattern of methylation. The cell is known to contain a multiplicity of tRNAs accepting the same amino-acid—isoaccepting tRNAs. Thus a change could be due either to a change in the relative proportions of the different isoaccepting tRNAs, or to the synthesis of new species of tRNA. While the relative proportions may be similar in different tissues[13], there is evidence for a shift in the relative proportions[13,14], and also for a new species of tRNA[15] during carcinogenesis. The complex relationship between synthesis and methylation has been studied in the intact animal, while isolated enzyme systems have been used to study the methylases without the complication of concomitant synthesis.

Evidence for aberrant methylation of tRNA during carcinogenesis comes from four sources: (1) direct analysis of RNA; studies of methylation in (2) the intact animal and (3) isolated systems, and (4) studies of the action of the carcinogen ethionine which is an analogue of methionine.

The obvious direct approach to the analysis of RNA would be to determine the amount of each methylated base in each tRNA of each amino-acid, and to compare the results obtained for tRNA isolated from normal tissue, precancerous tissue and from tumours. Because so little tRNA is present in the cell, and because of the multiplicity of tRNAs, only mixed tRNA has been studied in this way. There is evidence that tRNA isolated from mammary adenocarcinoma and S180 ascites tumours in mice contains more methylated purines than does tRNA from normal mouse tissues[16]. Accurate quantitative estimation of minor bases in small amounts of tRNA is difficult, however. Apart from work on surgically removed gliomas[17] this approach has not been followed up.

As far as the intact animal is concerned, measurement of methylated bases in urine from patients with leukaemia gave some of the first evidence for an increased level of methylation of tRNA in tumours[18]. During catabolism of tRNA, most of the methylated bases are probably deaminated or otherwise degraded. 7-Methylguanine, however, is excreted unchanged from the rat, and is partly converted into 8-hydroxy-7-methylguanine in man. Most, possibly all, of the 7-methylguanine originates in tRNA, and an increased excretion therefore implies that tRNA is being degraded more quickly than normal, or that hypermethylated RNA is being degraded at the normal rate, or that both events occur. Greater than normal excretion was found in rats and mice carrying thymic lymphomas and mammary carcinomas[19] and in hamsters with tumours induced by adenovirus-12 (ref. 20). A recent survey has shown, however, that this is not general among cancer patients with solid-tumour cancer (personal communication from S. Mirvish). It is possible that, in some of the cases cited, the response is due to the viral nature of the disease, rather than to its being associated with malignancy. It is known that, either directly or indirectly, viral infection can cause a change in methylase activity[21,22]. The cell death which is often concomitant with carcinogenesis may also lead to an

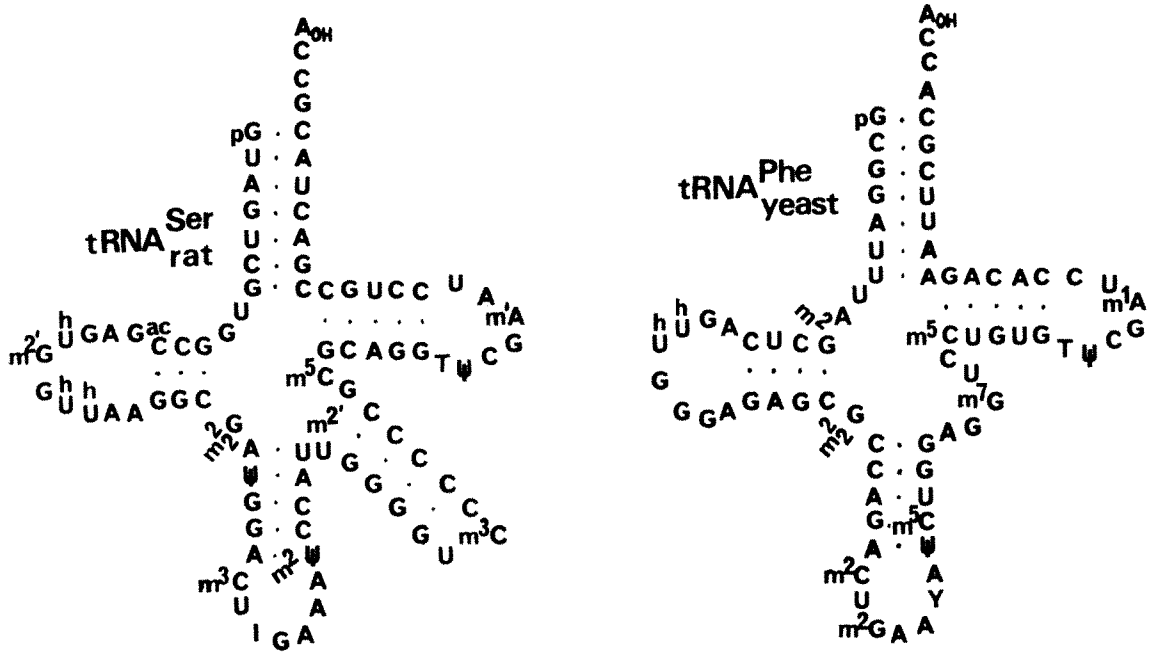

Fig. 1 Sequences of two tRNAs (from ref. 58).

increased excretion of methylated bases. Studies of urine therefore cannot give reliable information about the state of methylation of tRNA.

To study methylation of nucleic acids in the intact animal it is possible to give an injection of (^{14}C-methyl)-methionine, and later to kill the animal, isolate the tRNA, and after hydrolysis to analyse it for methylated bases. Normal rats and animals treated with several hepatocarcinogens have been studied in this way[9]. The methylated bases of normal liver become labelled within 2 h (Fig. 2*a*) after which the level of radioactivity slowly decreases, due to the slow turnover of tRNA. Liver tRNA from animals fed a diet containing dimethylnitrosamine for 23 weeks shows a much higher level of labelling of the methylated bases (Fig. 2*b*). This increase could possibly be due in part to an increased rate of total synthesis of tRNA, although this seems unlikely as there was no correspondingly large increase in synthesis of rRNA, DNA or protein. In addition, the different methylated bases increase in labelling to different extents, so that there is a change in their relative proportions. Similarly, in a rat which had been fed a diet containing aflatoxin, tRNA isolated from the liver tumour had a higher level of labelling of each of the methylated bases than had tRNA isolated from the liver lobes which had remained comparatively normal in appearance. Again the methylated base ratios from both samples differed from normal. Simultaneous measurement of synthesis and methylation by double-isotope techniques should help to elucidate these changes.

Isolated Systems

Crude extracts from various normal tissues and from cancerous tissue have been studied for their methylase activity, using *E. coli* tRNA as substrate and methyl-labelled S-adenosylmethionine as methyl donor. The level of activity has been studied by determining the rate of methylation of the substrate. The specificity of the enzymes has been investigated by measuring the maximum level of methylation which can be obtained when all susceptible sites have been methylated, that is, at the saturation level. A change in specificity might also be revealed by the fact that whereas normal methylases do not methylate their homologous tRNA when incubated *in vitro*, enzymes prepared from, for example, a liver tumour, might methylate normal liver tRNA.

Experiments of this type have given evidence for an increased activity and in some cases for an aberrant activity of methylases in various tumours, for example, in leukaemic leucocytes[23], Novikoff hepatoma[24], SV40-induced hamster tumours[25], mouse hepatoma[26], tumours induced by adenovirus-12 (ref. 27), tumours induced by viruses in chick liver[28], and neoplastic cell lines *in vitro*[29]. Methylases extracted from kidney tumours produced by injection of dimethylnitrosamine have also shown different properties from enzymes of normal kidney (my unpublished results). The kidney tumours were composed of a mass of light coloured cellular tumour, partly mixed with dark necrotic tissue. As far as possible, these tissues were homogenized separately, and their ability to methylate *E. coli* tRNA was studied (Fig. 3). A higher level of methylation was reached using an enzyme extract from the cellular tumour than from normal kidney or from the necrotic tissue. This suggests that specificity of the enzymes changes, but several complicating factors made interpretation of such results difficult.

First, there is the problem of the type of normal tissue to use as a control. In the experiments I have described, kidney tumours induced by dimethylnitrosamine were derived from mesenchymal cells (personal communication from G. C. Hard and W. H. Butler), and therefore connective tissue cells of the renal cortex would be a more appropriate control than normal kidney. Second, cellular changes in the tumour may alter the state of extractability of the methylase enzymes from the nucleus, and because it is often only the high-speed supernatant fractions from

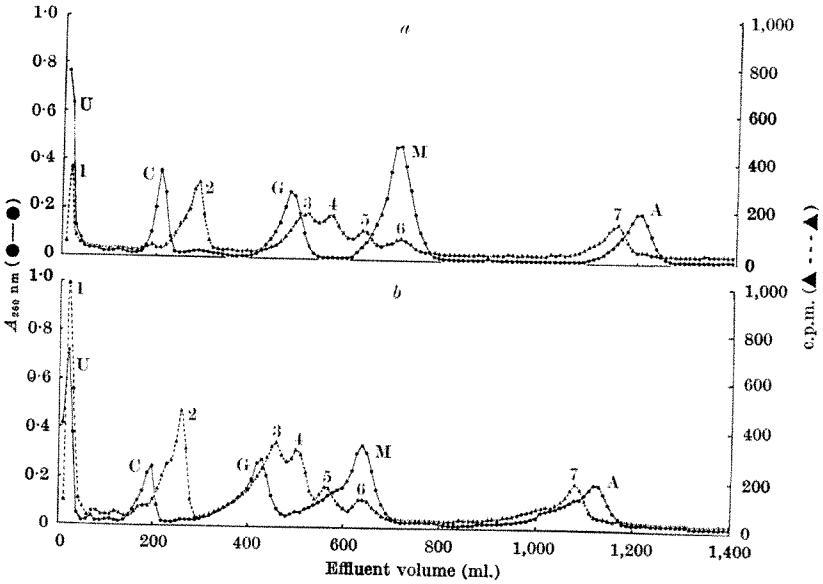

Fig. 2. Column chromatography on Dowex-50 of an $HClO_4$ hydrolysate of rat liver tRNA isolated after treatment with (^{14}C) methionine. *a*, Normal; *b*, after feeding the carcinogen, dimethylnitrosamine, in the diet for 23 weeks. A_{260} nm profile (●—●): U, uracil; C, cytosine; G, guanine; M, marker 7-methylguanine; A, adenine. Radioactivity profile (▲---▲): peak 1, methyluracil; peak 2, methylcytosine; peak 3, N^2-dimethylguanine; peak 4, N^2-methylguanine; peak 5, 1-methylguanine; peak 6, 7-methylguanine; peak 7, 1-methyladenine (*a* is taken from ref. 9).

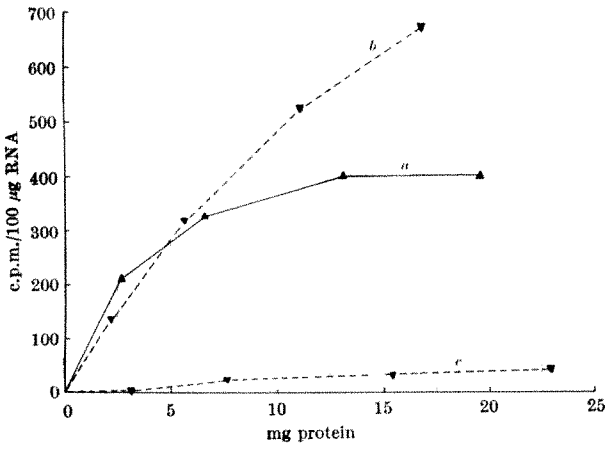

Fig. 3. Methylation of tRNA of *E. coli* K-12 during incubation with (^{14}C) adenosylmethionine and methylase preparations from (*a*) normal kidney; (*b*) cellular region of kidney tumour; (*c*) necrotic region of kidney tumour.

tissue homogenates which are studied, the results could be misleading. Furthermore, the presence of varying amounts of inhibitors[30] and activators[31] in tumours may alter the apparent enzyme activity. Ribonucleases present in crude methylase preparations may alter the tRNA during incubation in the assay procedure, making the substrate resistant to methylase activity, and thus causing a premature termination of methylation and a false plateau value.

It is therefore necessary, when studying methylase activity and specificity, to use enzyme preparations which have been at least partly purified. This has been done in the case of 1-methyladenine methylase from normal and leukaemic rat spleen[32,33]. The results supported the idea that there is a genuine increase in the amount of enzyme in leukaemic spleen, but no saturation level was reached when the purified enzyme was used in conditions which gave a plateau when crude extracts were used. Determinations of apparent saturation levels should be regarded as a preliminary stage in studies of the specificity of methylases.

More illuminating information concerning a possible change in specificity is given by determination of the sequence of bases around the methylated base. It was found that 1-methyladenine methylase from normal and from leukaemic spleen methylated adenine in the same tetranucleotide sequence[32]. Possibly analysis of a sequence longer than a tetranucleotide would have revealed a difference in specificities. More experiments of this type should show whether enzymes from normal and from tumour tissues have different actions on *E. coli* tRNA. The results would be more meaningful if tRNA from the same animal species could be used as substrate. If unmethylated precursor tRNA can be isolated from mammalian cells[34–36], this may be possible.

Ethionine Carcinogenesis

Ethionine is a potent hepatocarcinogen when given in appropriate doses in the diet. The mechanism of carcinogenesis of this analogue of methionine is of special interest in assessing the role of the nucleic acid methylases in carcinogenesis. After injection of ethionine, the ethyl group reacts with tRNA[37], but possibly not with rRNA or DNA[38]. Analysis of the tRNA shows that the ethyl group is probably attached to the base residues. One possible explanation is that ethionine is activated to form S-adenosylethionine (SAE), and that the methylase enzymes then use SAE in place of S-adenosylmethionine, so that tRNA is ethylated where it would normally have been methylated. There is also an increase in the level of methylase activity in the supernatant fraction of liver of mice fed ethionine[39] and of tumours induced by ethionine in rats[40]. Whether either this increase in methylase activity or the ethylation of tRNA is involved in carcinogenesis caused by ethionine is impossible to say at present.

In studies with most carcinogens which react with nucleic acids, reaction is found to occur with tRNA, rRNA and DNA, and the formidable problem is to determine which, if any, of these reactions is responsible for cancer. Only in the case of ethionine has reaction found to be almost entirely with tRNA. This is true even when the liver is rapidly synthesizing DNA and the nascent DNA is being methylated, as when ethionine is given to partially hepatectomized rats in a dose which does not inhibit regeneration (my unpublished results). Unfortunately, however, even in the case of ethionine, the carcinogen ethylates preformed protein[41] and is also incorporated as ethionine into protein[42]; possibly these reactions rather than those with tRNA are the carcinogenic event.

Biochemical Consequences of Altered Methylation

To assess the relevance of methylation of tRNA in carcinogenesis, and to decide whether a change in methylation is likely to explain the properties of cancer cells, it is necessary to understand the detailed functioning of tRNA. Conceivably, methylation of tRNA could affect any of the stages at which tRNA functions in protein synthesis, that is, in the acceptance of the appropriate activated amino-acid, in binding to the ribosome–mRNA complex, and in codon recognition. Methylation of the bases may alter their hydrogen bonding and stacking properties, and so alter the secondary and tertiary structure of the molecule, thus affecting each of these reactions. But it has been a working hypothesis that each activity of tRNA is associated with a definite region of the molecule. Then whether or not an activity is affected by hyper or hypomethylation will depend on whether or not the appropriate region contains a methylated base.

With reference first to the acceptor function, the sites on the clover leaf recognized by the amino-acyl tRNA synthetases have not yet been located. These sites could contain methylated bases, in which case methylation could affect charging of tRNA. There was evidence that methyl-deficient phenylalanyl tRNA had a lower rate of acceptance of phenylalanine than had the normal tRNA[43]. This result was not confirmed[44], however, when rigorous methods were used to avoid degradation of tRNA by nuclease activity during the separation of methyl-deficient from normally methylated phenylalanyl tRNA. In the case of ribosome dependent binding to mRNA, it has been suggested that, because the sequence TψCGp in the ψ loop is common to many tRNAs, this may be the ribosome binding site. Thus methylation of uracil to form thymine in this position might be essential for binding to occur. There is evidence that binding of leucine tRNA[45] and phenylalanyl tRNA[46] is reduced if the nucleic acid is deficient in methyl groups. Of most interest in relation to carcinogenesis is the possible effect of methylation on codon recognition. Sequence analysis has shown that the base next to the anticodon is often a methylated or otherwise modified rare base. Whether or not this

base is modified may determine the nature of the codon recognition, and thus determine which amino-acid is inserted into the protein chain, and thus the type of protein synthesized. Experimentally, however, the effect of methylation at this site has yet to be demonstrated.

Possible Significance for Carcinogenesis

There is good evidence that certain tumours have a higher level of methylase activity than do related normal tissues, although the increase may not occur in the early stages of the disease. Many enzymes are known to alter in activity during carcinogenesis[47] and so the problem is to determine whether any particular change is relevant to cancer or not. With reference to the nucleic acid methylases, the increase in activity is possibly specific for methylases of tRNA. There is evidence that the activity of rRNA methylases[9] and DNA methylases[48] does not change during carcinogenesis, although these enzymes have not been studied in detail. If tRNA is normally fully methylated soon after synthesis, it is difficult to assess the effect of an increase in methylase activity, unless there is at the same time a change in specificity of the enzymes. As I have discussed, the evidence for such a change is far from conclusive.

When the methylase enzymes were discovered it was suggested that they may play a part in differentiation. Some evidence for this has come from experiments on systems in which cell differentiation is taking place, for example, during insect metamorphosis[49], during morphogenesis of the slime mould[50], and in developing foetal rat brain[51]. The amount of work done so far is too limited for the suggestion to be more than an attractive hypothesis. Another idea is that methylase activity is related more to growth and protein synthesis. Thus there is a high concentration of methylases not only in tumours but also in embryonic liver[52] and in chick oviduct[53] and mouse mammary gland[54] after stimulation by hormones. On this basis one might expect to find high levels of activity in regenerating liver. Determination of methylase activity in samples of regenerating liver gave no evidence for this[55], although *in vivo* experiments showed that the ratio of synthesis to methylation of tRNA decreased at that time after partial hepatectomy when protein synthesis increases[56]. The relation between rate of protein synthesis, tRNA synthesis and methylation of tRNA is not clear, and the sites at which control mechanisms might act are unknown. At present there is no compelling evidence for either nuclear or cytoplasmic control of differentiation or of protein synthesis in eukaryotic cells. There is simply a good case for not continuing to look "too hard at the nucleus and not hard enough at the cytoplasm"[57].

In view of the lack of information concerning the control of differentiation and of protein synthesis, including the uncertainty of the part played by tRNA, it is only worthwhile to speculate very briefly on the significance of changes in tRNA methylases during carcinogenesis. There are two possibilities. One is that a change in methylase activity affects the synthesis of a specific regulator protein. Loss of such a protein may result in uncontrolled cell division, and thus start the carcinogenic process. Alternatively, changes in methylases may not be involved in the primary initiation of cancer but may be an essential part of the subsequent stages of the process. It now seems certain that carcinogenesis is not a one or two stage event, but that a multi-stage process causes the gradual evolution of cancer cells. The changes in protein synthesis which must occur during this process may be mediated by the changes in methylase activity. All that can be said with certainty is that there are alterations in methylase activity and possibly in specificity; the fact that these enzymes act on molecules concerned in what could be a key stage of gene translation is a compelling reason for finding out how these changes are brought about, and what their biological consequences may be.

Homogeneous preparations of initiation factor F_3 have both RNA binding and ribosome dissociation activities. But although DF activity could entirely account for the role of F_3 in the ribosome cycle this factor has an additional function in formation of the initiation complex that may be related to its RNA binding properties.

INITIATION factors of *Escherichia coli* (F_1, F_2, F_3) are loosely associated with 30S ribosomal subunits[1,2] and can be extracted by washing the ribosomes with concentrated salt solutions, such as 1·0 M NH_4Cl (refs. 3 and 4). F_2 has essential SH groups[5] and mediates the binding of the initiator, fMet-$tRNA_f$, to a messenger–30S ribosome subunit complex[3,6]. This reaction requires Mg^{2+} and GTP and is accompanied by hydrolysis of GTP[6–8]. When the trinucleoside diphosphate ApUpG (AUG) is used as messenger in conditions where F_3 is not required, the AUG–30S–fMet-$tRNA_f$ complex can be formed at 0° C with F_2 as the only initiation factor, but at 25° C both F_1 and F_2 are essential[6]. This suggests that the complex formed in the absence of F_1 is very unstable and is stabilized when F_1 is present. A requirement for F_3, both for translation and formation of the initiation complex[3], is found when natural mRNA (such as phage RNA) is used as messenger. Our results[3] suggest that formation of the initiation complex involves two steps: (*a*) the F_1 and F_3-dependent binding of mRNA to the ribosomes, and (*b*) the F_2-dependent binding of fMet-$tRNA_f$ to the mRNA–ribosome complex.

All three initiation factors are now available in virtually homogeneous condition. The purification and properties of F_2 have been described[9] and the preparation of homogeneous F_1 has been reported[10]. We describe here the preparation of homogeneous, or nearly homogeneous, F_3 (see Fig. 1) and further studies on the properties and function of this factor. F_3 has an RNA binding activity, as judged by 'Millipore' filtration assays, and promotes dissociation of 70S ribosomes to 30S and 50S ribosome subunits[11]. Insofar as initiation requires the availability of 30S subunits[12] the dissociation factor activity of F_3 could account entirely for its role in the ribosome cycle[13,14]. But we show also that F_3 is directly involved in formation of the chain initiation complex.

The purification procedure is summarized in Table 1. Step 6 F_3 has an A_{280}/A_{260} ratio of 1·8, indicating that it is free of nucleic acid. Fig. 2 shows that it is an essentially homogeneous, basic protein as judged by disc electrophoresis at two *p*H values in 8·0 M urea and by SDS-gel electrophoresis. It is better than 90 per cent pure. When estimated by ultraviolet absorption the values are less than one-third, according to the Lowry method. Because of this exceptional discrepancy the protein concentration of step 6 F_3 solutions was also determined refractometrically[17] and gravimetrically. For the latter measurement the protein, extensively dialysed against NH_4HCO_3 solutions, was lyophilized, then repeatedly dissolved in water and relyophilized to constant weight. The relative values given by the four methods were: Lowry, 1·0; gravimetric, 0·93; refractometric, 0·87; ultraviolet absorption, 0·32. Lowry values will be used throughout unless otherwise stated.

† 1 unit = 1·0 nmole of ^{14}C-lysine incorporated under standard assay conditions (20 min, 37°).
‡ Units/mg protein.
§ Peak fractions.

The standard assay of F_3 is described in the legend to Fig. 1. In the conditions of the assay, the incorporation of ^{14}C-lysine into acid-insoluble material was proportional to the concentration of F_3 up to about 2·0 μg/0·125 ml. Protein was determined by the method of Lowry *et al.*[16] using bovine serum albumin as a standard. Blanks in the absence of F_3 averaged 0·07 nmole and in the absence of MS2 RNA (with 2·5 μg F_3) 0·02 nmole. Omission of F_1 and F_2 still permitted significant incorporation (about 0·26 nmole with 2·5 μg F_3). We isolate the three initiation factors from the 1·0 M NH_4Cl wash of unfractionated *E. coli* Q13 ribosomes. All operations are carried out at about 4° C. The wash, obtained as previously described[3], was fractionated with ammonium sulphate. The precipitate between 55 and 70 per cent saturation (at 4° C), containing the bulk of F_1 and F_3, was dialysed against 0·005 M phosphate-Tris-glycerol (PTG) buffer (0·005 M phosphoric acid with Tris base added to *p*H 7·5, 5 per cent glycerol). Phosphate was used in all buffers because it has a stabilizing effect on F_3. The dialysed solution was diluted with the same buffer to 10 mg protein/ml. and applied to a column (3 × 70 cm) of DEAE-SH cellulose (Serva, 0·8 mequiv/g) equilibrated with the same buffer. F_1 is not retained by DEAE-cellulose. The column was washed with this buffer until the A_{280} of the effluent was near zero and F_3 was eluted with 0·15 M PTG buffer (0·15 M phosphate). F_3 activity was found in the initial fractions. These were pooled and dialysed against 0·1 M phosphate-Tris-sucrose (PTS) buffer (0·1 M phosphoric acid with Tris base added to *p*H 7·5, 10 per cent sucrose). The dialysed solution was applied to a column (2·2 × 48 cm) of phosphocellulose (Serva, 0·68 mequiv/g), previously washed with 25 per cent NaCl and equilibrated with 0·1 M PTS buffer. Washing with the same buffer until the A_{280} of the effluent was near zero removed large amounts of inactive protein. F_3 was then eluted with 0·5 M PTS buffer (0·5 M phosphate). The active fractions were pooled, the protein concentrated by precipitation with ammonium sulphate at 80 per cent saturation, and the precipitate dissolved in a minimal volume of 0·5 M PTS buffer (0·5 M phosphate). This solution was chromatographed on a column (2·5 × 88 cm) of 'Sephadex G100' equilibrated with 0·5 M PTS buffer. F_3 activity coincided with a protein peak eluting about 100 ml. after the void volume. The pooled active fractions were concentrated either by dialysis against saturated ammonium sulphate or by chromatography on a small phosphocellulose column. At this stage (step 5) polyacrylamide gel electrophoresis revealed a broad, fuzzy band in the absence of urea and two sharp bands in 8·0 M urea. Further purification (step 6) was carried out by 'Sephadex' chromatography in 6·0 M urea; brief exposure to this concentration of urea does not inactivate F_3. The concentrated solution from step 5 was dialysed against a buffer (PTU-SH buffer) containing 0·1 M phosphoric acid, with Tris base to *p*H 7·5, 6·0 M deionized urea, and 0·002 M dithiothreitol, and the dialysed solution applied to a column (1·5 × 88 cm) of 'Sephadex G75' equilibrated with the same buffer. On elution with this buffer the F_3 activity coincided with the principal A_{280} peak which emerged from the column at a volume slightly greater than the void volume. Appropriate peak fractions were pooled and dialysed at once against 0·5 M PTS buffer. When kept in this buffer at 4° C, F_3 is stable for several months. Two preparations of F_3 by the method described gave essentially identical results. F_3 can be lyophilized salt-free after dialysis against NH_4HCO_3 solutions without substantial loss of activity. The lyophilized material is stable at refrigerator temperatures and can be redissolved with retention of activity for one week in a phosphate-free buffer containing 0·25 M Tris-HCl (*p*H 7·8)–10 per cent sucrose.

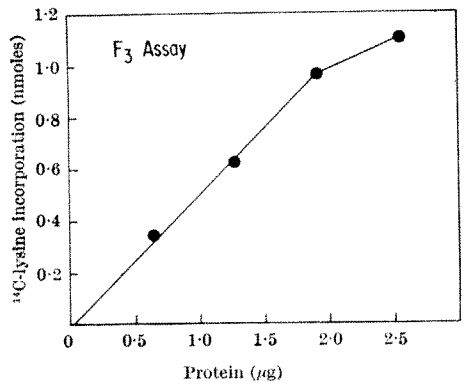

Fig. 1. F_3 assay. Assay is based on F_3 dependence for translation of mRNA by 1·0 M NH_4Cl-washed *E. coli* Q13 ribosomes in the presence of excess F_1 and F_2. The samples contained, in a volume of 0·125 ml., Tris-HCl buffer (*p*H 7·8), 60 mM; phosphate buffer (*p*H 7·8), 4 mM; NH_4Cl, 70 mM; magnesium acetate, 14 mM; 2-mercaptoethanol, 16 mM; ATP, 1·3 mM; GTP, 0·3 mM; phosphocreatine, 17 mM; creatine kinase, 3 μg; tRNA (*E. coli* W), 55 μg; MS2 RNA (as messenger), 1 A_{260} unit (about 40 μg); purified ribosomes, 5 A_{260} units (about 200 μg RNA); *E. coli* Q13 s150 supernatant (as a source of amino-acyl-tRNA synthetases, chain elongation and chain termination factors) with about 0·3 mg protein; F_1 (about 50 per cent purity), 2 μg; F_2 (about 10 per cent purity), 40 μg; F_3 (about 75–80 per cent purity), from 0·64 to 2·56 μg; ^{14}C-lysine (specific radioactivity 10 μCi/μmole), 0·1 mM; and the remaining (unlabelled) 19 amino-acids, each 0·1 mM. After incubation (20 min, 37° C) acid-insoluble radioactivity was determined as previously described[3]. The blank in the absence of F_3 (about 0·07 nmole) was subtracted. Lysine incorporation in the presence of F_3 2·5 μg) but without F_1 and F_2 averaged 0·26 nmole; with all three factors (2·5 μg F_3) but without MS2 RNA it averaged 0·02 nmole.

procedure of Ellman[19]. The results were the same with native F_3 or with F_3 exposed either to 8·0 M urea for 1 h at 30° C or to 1 per cent SDS for 2 h at 37° C. The molar ratio bound DTNB/F_3 was about 0·6 on the basis of Lowry protein (about 0·7 on a refractometric protein basis). Thus F_3 seems to contain one reactive SH group. Preincubation of the factor with 10–20 mM N-ethylmaleimide resulted in moderate inhibition (~40–50 per cent) of its activity. The degree of inhibition, however, was about the same in the standard MS2 RNA translation assay and in the RNA binding and DF assays described below. This suggests that these activities reside in the same protein.

When labelled RNA or synthetic polynucleotides are incubated with F_3, as described in Fig. 3, the retention of label on 'Millipore' filters is proportional, if within narrow limits, to the concentration of F_3. Fig. 3 shows that peaks of RNA binding and amino-acid incorporation activity overlap the principal protein peak on chromatography of step 5 F_3 on 'Sephadex G75' in 6·0 M urea. The same is true of DF activity although, in the case of Fig. 3, this was ascertained for only three of the fractions. F_3 is not the only protein in the ribosomal wash that has RNA binding activity. We have seen other fractions with similar properties although without F_1, F_2 or F_3 activity. Fig. 3 also shows that the small protein peak between fractions 45 and 60, which is devoid of F_3 activity, has some RNA binding activity. A protein with similar RNA binding properties has been isolated by Brown and Doty[20] from the 1·0 M NH_4Cl wash of *E. coli* ribosomes. We have tested this protein (kindly provided by Dr Brown) for activity in fMet-tRNA$_f$ binding and mRNA translation, but with negative results. The RNA binding activity of F_3 cannot be solely ascribed to its basic nature because F_1, a more basic protein, lacks this property. F_2 is also inactive in the RNA binding assay.

Davis[21] predicted the occurrence of a factor causing dissociation of 70S ribosomes (ribosome dissociation factor, DF) and suggested that it would function in chain initiation by providing a supply of 30S subunits. DF activity is found in crude preparations of initiation factors[22,24,25]. Fractionation of the factors by DEAE-cellulose chromatography[3] showed that DF is associated with F_3 (ref. 11), a finding that we have confirmed with highly purified F_3 preparations[11,23]. The DF activity of step 6 F_3 is show in Fig. 4. In this experiment, 2·6 μg F_3 promoted ov 75 per cent dissociation of 40 μg ribosomes. By contra (Fig. 4) 14 μg of crystalline F_1 had no activity[12]. In oth experiments, F_2 was found to be free of DF. The results are incompatible with a recent suggestion b Miall *et al.*[26] that DF activity is associated with t initiation factor F_1. The reported DF activity of this preparation, however (judged to be about 95 per ce pure), is probably the result of contamination with for it amounts on a molar basis to only 5–10 per cent t DF activity of our step 6 F_3. According to so workers[11,24] DF activity is stimulated by GTP. In o assay conditions, however, we found no effect of GT on the dissociation reaction[23]. Similar results we reported from two other laboratories[25,26].

Chain Initiation

Stimulation by F_3 of mRNA translation and formatic of the initiation complex in experiments with unfra tionated ribosomes[3], containing a fairly large proportic of 70S particles, could be indirect and caused entire by its DF activity. But, using 30S subunits, or a mixtu of 30S and 50S subunits that do not reassociate spo taneously, shows that this factor is also directly involv in chain initiation. We have analysed the factor requi ments for initiation complex formation with ^{3}H-M RNA, ^{14}C-methionine labelled fMet-tRNA$_f$ and no spontaneously reassociating 30S and 50S ribosomes zonal centrifugation in sucrose gradients with use homogeneous or nearly homogeneous F_1, F_2 and F_3.

As shown in Fig. 5, a 70S complex was formed only the presence of the three factors. Panel *D* shows t appearance of an absorbance shoulder in the 70S regi of the gradient with overlapping peaks of ^{3}H and radioactivity. Similar results are obtained if F_1 omitted[3] but in this case the extent of complex formati is 50 per cent or less of that observed with the th factors. In particular, no complex was formed in t absence of F_3 (see panels *A* and *B*). With F_1 and

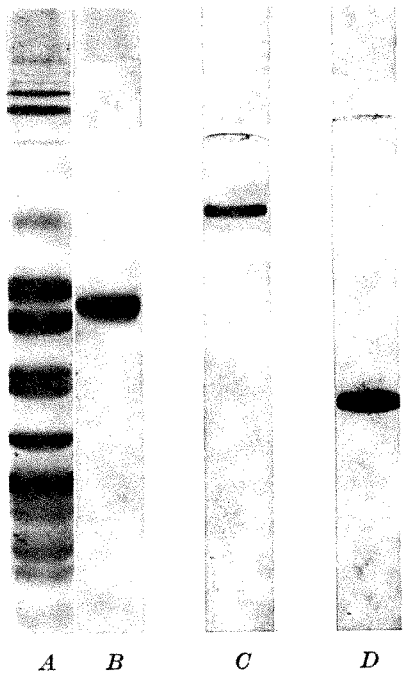

Fig. 2. Polyacrylamide gel electrophoresis of F_3 (step 6). *A* and 8·0 M urea (*p*H 4·5) (origin at top, cathode at bottom); *A*, protei (about 30 μg) from 1·0 M NH_4Cl-washed 30S ribosomes; *B*, F_3 (abo 8 μg). *C*, F_3 (about 7 μg), *p*H 12·7, 8·0 M urea (origin at top, anode bottom). *D*, F_3 (about 5 μg), SDS gel electrophoresis, *p*H 7·0 (orig at top, anode at bottom). Disc electrophoresis in 8·0 M urea was carri out as previously described[3] and SDS-gel electrophoresis as describ by Weber and Osborn[16].

alone (panel *C*) there was a small shoulder in the ^3H radioactivity curve in the region between 30S and 50S and the absorbance trough in this region was less deep than in the other panels. This may reflect formation of a 30S–MS2 RNA complex in the presence but not in the absence of F_3 (see panel *B*). Because the sedimentation coefficient of MS2 RNA is about 28S, such a complex might sediment somewhat faster than 30S. Little or no 70S complex was formed in control experiments without MS2 RNA, 30S subunits, or on substitution of uncharged tRNA for fMet-tRNA[28]. Thus, in the conditions of the present experiments, joining of 30S and 50S ribosomes requires formation of a complete initiation complex including both mRNA and fMet-RNA_f. This lends further support to the view[12–14,29] that joining of the ribosomal subunits to a 70S couple directly follows the formation of the initiation complex on the 30S ribosome. In the experiment of Fig. 5 one starts with fully dissociated ribosomes and that, despite its DF activity, F_3 promotes formation of 70S ribosomes (see panels *B* and *D*).

Direct involvement of F_3 in formation of the initiation complex can also be shown with 30S subunits. In the experiment of Table 2, ribosomal binding of ^{14}C-methionine-labelled fMet-$tRNA_f$, in the presence of unlabelled MS2 RNA, was measured by the 'Millipore' filter technique[30].

Initiation Factors and the Ribosome Cycle

Our results suggest a dual function for F_3 in the ribosome cycle shown schematically in Fig. 6: (*a*) to ensure a supply of 30S subunits at or after chain termination (step 5); and (*b*) direct involvement in initiation (step 1). Some workers believe that chain termination liberates 70S ribosomes[11,31] which dissociate subsequently[11] by interaction with F_3 released from 30S subunits when the 50S subunit joins the 30S initiation complex (step 3). This would imply that F_3 recycles between a ribosome-bound and a free form. Other workers hold the view that the ribosomes dissociate at chain termination[13,32]. If so, F_3 might remain ribosome-bound throughout the entire cycle so long as ribosomes bearing F_3 can associate and remain associated when they carry aminoacyl- or peptidyl-tRNA[25]. At present, the precise manner in which F_3 functions in the ribosome cycle remains an open question.

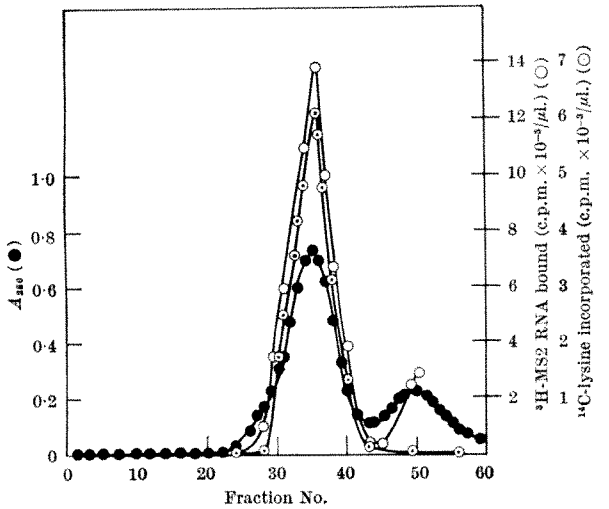

Fig. 3. Amino-acid incorporation and RNA binding activity of F_3. Chromatography of step 5 F_3 on 'Sephadex G75' in 6·0 M urea. Effluent fractions assayed for (*a*) translation of MS2 RNA in the standard F_3 assay (^{14}C-lysine incorporation) and (*b*) retention of ^3H-MS2 RNA on 'Millipore' filters (RNA binding). Some fractions were also assayed for DF activity (see Fig. 4). The percentage dissociation of 70S ribosomes was 38, 75 and 28 with aliquots (1 μl.) of fractions of No. 31, 35, and 40 respectively. For the RNA binding assay, the samples contained, in a final volume of 0·105 ml., phosphate buffer (*p*H 7·5), 20 mM; bovine serum albumin, 0·1 mg; ^3H-MS2 RNA, 2 μg (about 14,000 c.p.m.) and sample to be assayed (for step 6 F_3 with 0·2 to 0·9 μg protein). After incubation for 20 min at 0° C, 1 ml. of 0·1 M PTG buffer was added, the mixture was filtered through 'Millipore' membranes, at the rate of 1 ml./15 s, and the radioactivity retained on the filter measured.

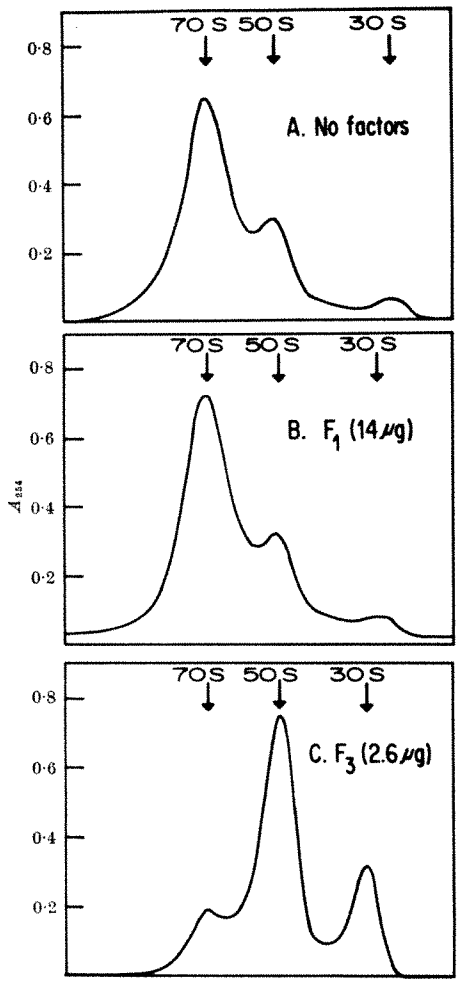

Fig. 4. Ribosome dissociation activity (DF activity) of F_3. The assay was carried out with 1·0 M NH_4Cl-washed *E. coli* MRE 600 ribosomes. The ribosomes were preincubated for 15 min at 37° C in a buffer containing 50 mM Tris-HCl (*p*H 7·8), 5 mM magnesium acetate and 1 mM dithiothreitol (DTT). The assay samples contained, in a final volume of 0·125 ml., Tris-HCl buffer (*p*H 7·8), 50 mM; phosphate buffer (*p*H 7·8), 4 mM; NH_4Cl, 40 mM; magnesium acetate, 6·6 mM; DTT, 1 mM, and preincubated ribosomes, 0·8 A_{260} unit (32 μg RNA), with or without factors as indicated. Homogeneous F_3 (step 6) and F_1 were used. After incubation at 37° C for 20 min, 0·1 ml. of the incubation mixture was layered on 5 ml. of a 5–20 per cent sucrose gradient containing 50 mM Tris-HCl buffer (*p*H 7·8), 60 mM NH_4Cl and 4 mM magnesium acetate, and centrifuged for 2 h at 4° C and 37,000 r.p.m. in the Spinco SW 39 rotor. The gradients were analysed in an Isco (model D) gradient analyser using a 10 mm light path flow cell.

At which step in initiation is F_3 directly involved? Our previous experiments with unfractionated ribosomes[3] were interpreted to mean that F_3 functions, along with F_1, in mRNA binding (Fig. 6, step 1). These experiments were similar to those of Fig. 6 except for the preparation of ribosomes and the use of ^{32}P–Qβ RNA as messenger. With F_1 and F_3 alone a peak of mRNA radioactivity appeared under the 70S ribosomal peak, but there was no

Table 2. EFFECT OF INITIATION FACTORS ON MS2 RNA-DEPENDENT RIBOSOMAL BINDING OF fMet-$tRNA_f$ WITH 30S RIBOSOMES

Factor additions (μg)	fMet-^{14}C-tRNA binding (pmoles) 30S	30S + 50S
None	0·09	0·05
F_3 (2·6)	0·15	0·08
F_1 (1·2), F_3 (2·6)	0·62	0·31
F_1 (1·2), F_3 (2·6), F_3 (1·1)	3·20	4·62

Samples contained, in a final volume of 0·125 ml., Tris-HCl buffer (*p*H 7·8), 50 mM; NH_4Cl, 60 mM; magnesium acetate, 5·4 mM; GTP, 0·16 mM; MS2 RNA, 1 A_{260} unit; fMet-^{14}C-tRNA, about 16 pmoles fMet-$tRNA_f$ (about 4,000 c.p.m.); and either 30S, 2 A_{260} units (left column), or 30S, 1 A_{260} unit, and 50S, 2 A_{260} units (right column), ribosomes. Incubation: 15 min at 37° C, 'Millipore' assay. The subunits were prepared as described for Fig. 5. F_1, F_3 and F_3 were homogeneous preparations.

significant binding of fMet ^{14}C-tRNA$_f$ unless F_2 was also present. The observed association of mRNA with 70S ribosomes, in the absence of substantial fMet-tRNA$_f$ binding, could result if non-specific binding of uncharged tRNA, present in the preparations of fMet-tRNA, permits joining of the 50S ribosome to the 30S–mRNA complex[13]. But, in any case, there is little doubt that F_3 promotes binding of mRNA to the ribosomes, an activity that may well be related to the RNA binding property of F_3 described here. This effect of F_3 is always markedly augmented by F_1. For this reason we believe that F_1 also functions at this stage of initiation (Fig. 6, step 1). Moreover, at 25° C, F_1 is essential for the AUG-dependent binding of fMet-tRNA$_f$ to 30S subunits[6]. In this system F_1 decreases the K_m for AUG (unpublished work of R. Mazumder), suggesting that this protein stabilizes mRNA binding to the ribosome. Thus, there seems to be little basis for the assumption[34] that F_1 is active in joining 50S subunits to the 30S initiation complex because of its apparent failure to stimulate AUG- and F_2-dependent binding of fMet-tRNA$_f$ to 30S subunits.

Finally, as regards F_2, work in this and other laboratories demonstrates that this factor functions specifically in the mRNA-dependent binding of the initiator fMet-tRNA$_f$ to the 30S subunit. We see no indications from our previous[3] or present work (Fig. 5*B*) that F_2 participates in the binding of mRNA to the ribosome. Thus, we believe that F_2 is involved at step 2 (Fig. 6) of the ribosome cycle. A reported stimulation by F_2 of mRNA binding to 30S subunits[34], if not arising from impurities, may reflect the occurrence of non-specific interactions in certain conditions.

We thank Mr Horace Lozina for growing bacterial cells, Mr Morton C. Schneider for preparation of unlabelled and ^{3}H-labelled MS2 RNA, Miss Maryanne Pendergast for the photograph used in Fig. 2, and Dr R. Mazumder and Dr W. Szer for discussions and Mr F. Zaboretsky for the refractometric protein determination. The work was aided by

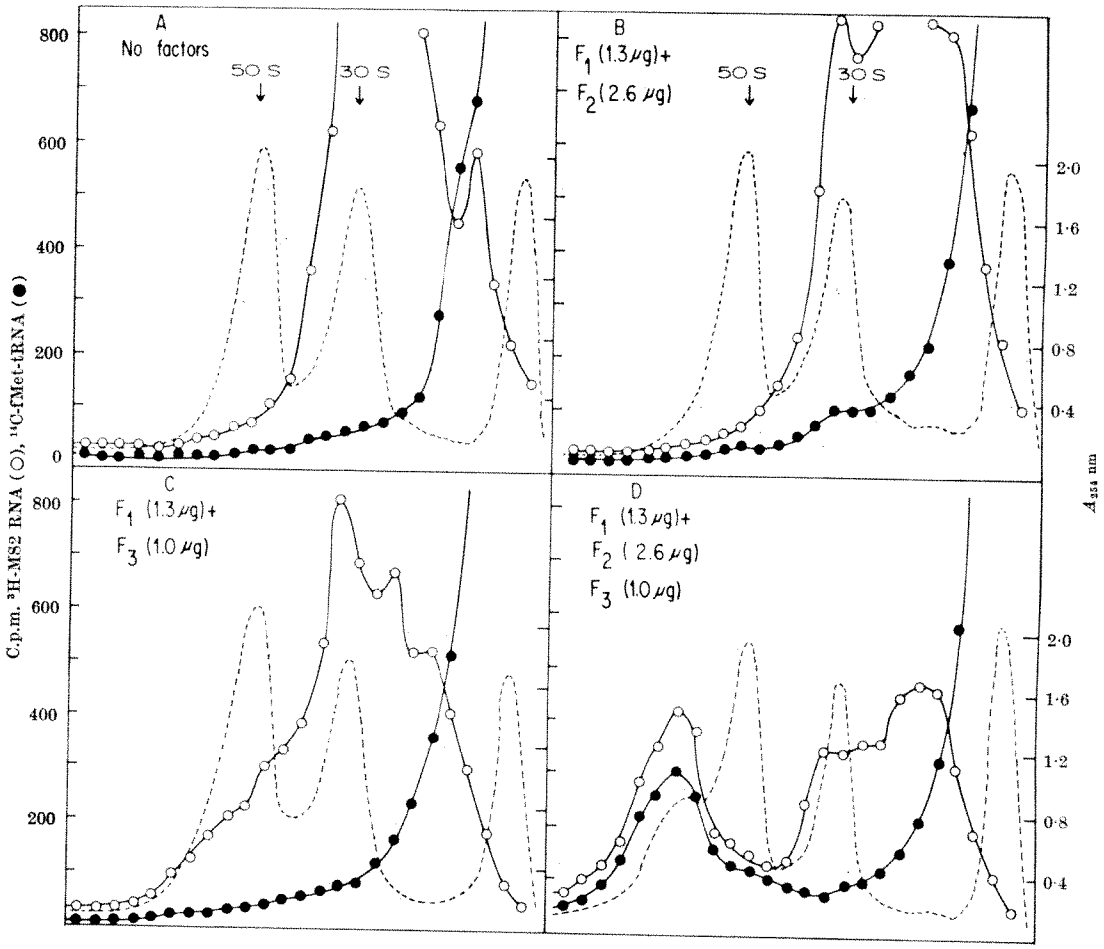

Fig. 5. Effect of initiation factors on formation of the chain initiation complex with non-spontaneously associating 30S+50S ribosomal subunits. Complex formation, using ^{3}H-MS2 RNA and ^{14}C-methionine-labelled fMet-tRNA, was analysed by zonal centrifugation in sucrose gradients. The subunits were prepared as follows: *E. coli* Q13 ribosomes were washed for 10 h at 4° C with a buffer containing 20 mM Tris-HCl (*p*H 8·1), 10 mM magnesium acetate and 1·0 M NH_4Cl. The ribosomes were sedimented by centrifugation at 4° C for 3 h at 60,000 r.p.m. in the Spinco 65 rotor, washed in the above buffer for a further 5 h, sedimented as before and suspended in 20 mM Tris-HCl (*p*H 7·8)—5 mM magnesium acetate—0·1 mM DTT—50 mM NH_4Cl (buffer A). The subunits were isolated by centrifugation through 50 ml. of a linear 10–30 per cent sucrose gradient in buffer A. The gradients were equilibrated for 8 h at 4° C, loaded with 1·5 ml. sample containing 300 A_{260} units of purified ribosomes (previously incubated for 5 min at 37° C in buffer A) and centrifuged for 11 h at 4° C and 24,000 r.p.m. in the SW 25·2 rotor of the Spinco L-2 centrifuge. The bands of 30S and 50S subunits could be easily seen through light scattering and the subunits recovered by suction. After adjusting the Mg^{2+} concentration of the ribosomal suspensions to 20 mM, the subunits were concentrated by centrifugation for 8 h at 4° C and 50,000 r.p.m. in the Spinco 65 rotor. The pellets were resuspended in a buffer containing 20 mM Tris-HCl (*p*H 7·8), 10 mM magnesium acetate and 0·5 M NH_4Cl and stored at 4° C. Before use the subunits were activated[27] by incubation for 2 min at 50° C in 10 mM Tris-HCl (*p*H 7·8)—250 mM NH_4Cl—30 mM magnesium acetate. The samples contained, in a final volume of 75 μl., Tris-HCl buffer (*p*H 7·8), 50 mM; NH_4Cl, 80 mM; magnesium acetate, 4·2 mM; GTP, 0·13 mM; DTT, 0·8 mM; ^{3}H-MS2 RNA, 0·58 A_{260} unit (about 8,500 c.p.m.); fMet ^{14}C-tRNA, about 20 pmoles fMet-tRNA$_f$ (about 5,000 c.p.m.); 30S ribosomes, 0·9 A_{260} units; 50S ribosomes, 1·9 A_{260} units, with or without homogeneous factors as indicated. After incubation for 15 min at 37° C, 60 μl. aliquots were layered on 5 ml. of a 5–20 per cent sucrose gradient, containing 50 mM Tris-HCl buffer (*p*H 7·8), 60 mM NH_4Cl, 5 mM magnesium acetate, and centrifuged for 55 min at 4° C and 63,000 r.p.m. in the Spinco SW 65 rotor. The gradients were analysed in an Isco gradient analyser (as in Fig. 4) attached to a fraction collector.

Activity of Initiation Factor F_3 in Dissociating *Escherichia coli* Ribosomes

by
A. R. SUBRAMANIAN
BERNARD D. DAVIS
Bacterial Physiology Unit,
Harvard Medical School,
Boston, Massachusetts 02115

Pure initiation factor F_3 dissociates 70S ribosomes into 30S and 50S subunits in a way which suggests that *in vivo* interaction with runoff ribosomes is responsible for their dissociation into subunits.

When the products of polysome runoff are caused to accumulate in *Escherichia coli* cells or extracts they appear as 70S ribosomes[1]; and such "free" runoff ribosomes differ from complexed monosomes carrying messenger RNA and nascent polypeptide, in being more easily dissociated by low Mg^{2+} concentrations[2] or by Na^+ (ref. 3). Because runoff causes no parallel increment of ribosomal subunits, and because subunits are required for initiation of protein synthesis[4], this implies that the dissociation step in the ribosome cycle does not occur spontaneously. We have suggested that runoff ribosomes must complex with a dissociation factor, which would be present in the cell in limiting supply and would have to recycle, in the course of initiation, from a completed initiation complex to another free ribosome[1]. We have found this dissociation factor (DF)[5] in the mixture of initiation factors obtained by extracting the 30S ribosomal pellet with 1 M NH_4Cl; and as required for its proposed function, it dissociates free but not complexed (polysomal) ribosomes[5–8].

Because NH_4Cl-washed 70S ribosomes can perform all the steps in initiation with a mixture of three known initiation factors[9,10], dissociation factor must be one or more of these factors. Indeed, separation of the initiation factors on DEAE-cellulose regularly yields a good recovery of DF activity in the F_3 fraction, while lower activities appear variably in the F_1 fraction[6,11]. Identity of DF with F_3 is further strongly supported by our finding that with

purified preparations of the three initiation factors[12], kindly provided by Dr S. Ochoa, the F_3 preparation causes dissociation but F_1 and F_2 do not[6].

Dr Ochoa has now kindly provided us with an essentially pure preparation of F_3, described in the preceding article[13]; and we have confirmed the observation that this material is active in dissociating ribosomes. As a further test of the physiological significance of the reaction we have examined its stoichiometry at low Mg^{2+} concentrations when the response is maximized[5]. Our results support the conclusion that F_3 is the factor responsible for the dissociation step in the ribosome cycle.

Dissociation of Free 70S Ribosomes by Factor F_3

Fig. 1 shows the effect of pure F_3 on the sedimentation pattern of NH_4Cl-washed ribosomes in a buffer containing 2 mM Mg^{2+}. Incubation of 30 μg of ribosomes with 0·5 μg of F_3 raised the level of subunits from an initial value of 15 per cent to a final value of 60 per cent and 1·0 μg raised it to 90 per cent.

The number of 70S particles dissociated by a given amount of unpurified dissociation factor depends strongly on the concentration of Mg^{2+} (ref. 5). Because free *E. coli* ribosomes dissociate spontaneously at Mg^{2+} concentrations below 1·5 mM* (in the presence of 10 mM Tris and 50 mM KCl), our earlier standard assay used 5·0 mM Mg^{2+} (plus 1 mM GTP) to provide a safe margin against spontaneous dissociation. To measure the dissociating capacity of pure F_3 under more optimal conditions it was tested at various lower Mg^{2+} concentrations down to the level of incipient spontaneous dissociation. As Fig. 2 shows, while 2 μg of F_3 gave only about 15 per cent dissociation of 25 μg of 70S ribosomes at 5·0 mM Mg^{2+} it gave nearly 100 per cent at 2·0 mM. Smaller amounts of F_3 yielded parallel curves.

Unwashed runoff ribosomes responded to low Mg^{2+} or to F_3 very similarly to our ribosomes which had been washed with 1 M NH_4Cl after extraction from exponentially growing cells (Fig. 1)†. This shows that DF is not a ribosomal protein artificially extracted by 1 M NH_4Cl, but that it is physiologically detached from the ribosome at some stage before runoff. The distribution of DF among the various ribosomal particles[5] has suggested that the detachment occurs at some stage in the transition between an initiating complex and a functioning polysomal ribosome.

In Fig. 3 the data of Fig. 2 are redrawn to plot dissociation against amount of F_3. The curves obtained, at different Mg^{2+} concentrations, are each quite linear with F_3 up to at least 50 per cent dissociation. This result would be expected for a first-order reaction, in which one molecule of F_3 combines with a ribosome.

Because the molecular weight of F_3 is 21,200[13], and that of NH_4Cl-washed ribosomes is $2{\cdot}6 \times 10^6$ (ref. 15), a 1 : 1 stoichiometry would give 124 μg of ribosomes dissociated per μg of F_3. The ratios we observed at 2·0 and 1·5 mM Mg^{2+} are 28 and 53, respectively, which are equivalent to about 4 and 2 molecules of F_3 per ribosome. Moreover, from Fig. 2 it seems that even 1·5 mM Mg^{2+} is not low enough to permit a maximal response. These ratios, in a reaction that does not go to completion in the conditions of testing, also support the model in which one molecule of F_3 combines with the 30S moiety of a 70S ribosome and causes it to dissociate from the 50S moiety.

The dissociation reaction is strikingly inefficient at the Mg^{2+} concentrations optimal for *in vitro* protein synthesis with natural messenger (5·0 mM or above)—less than one tenth as efficient as at 1·5 mM. If the response is similar in the cell it would seem that a low affinity for DF is necessary in the ribosome cycle, perhaps to permit the binding of DF to be reversed on reassociation of the initiating 30S subunit with a 50S subunit.

The apparent affinity constant of F_3 for the ribosome at 4 mM Mg^{2+} can be calculated, from the 50 per cent dissociation of ribosomes in equilibrium with 2 μg/ml., as $(2 \times 10^{-3})/(22 \times 10^{3}) \approx 1 \times 10^{-7}$ M. This affinity, which seems very low in dilute solution, is still sufficient to cause most DF molecules to be bound in the cell. For in our assays the response in 4 mM Mg^{2+} on the linear part of the F_3 concentration curve corresponded to 1 DF molecule causing dissociation, and therefore bound, for about every twenty molecules not causing dissociation and hence presumably free. In these assays 25 μg of 70S ribosomes were incubated in 0·1 ml. of solution. Because the ribosome concentration in the cell is roughly 150 times as great, a similar equilibrium in the cell would yield a ratio of bound to free DF of about 8 : 1, which is consistent with our earlier failure[5] to detect any DF in the supernatant fraction of a lysate.

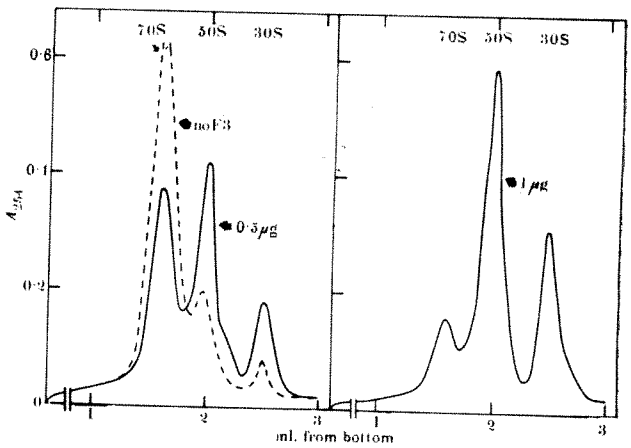

Fig. 1. Dissociation of 70S ribosomes by initiation factor F_3. Thirty μg of ribosomes (0·50 A_{260} unit), of which 25 μg was 70S particles, were incubated at 30° C with 0, 0·5, or 1 μg of F_3 in 0·1 ml. solution of 10 mM Tris-HCl (*p*H 7·8), 50 mM KCl, 2 mM magnesium acetate, and 2 mM dithiothreitol (DTT). After 15 min the mixture was chilled in ice and 0·08 ml. was layered on a 10–30 per cent sucrose gradient in TKM (10 mM Tris-HCl *p*H 7·8, 50 mM KCl, 5 mM magnesium acetate). The gradients were spun at 4° C for 1 h at 60,000 r.p.m. ($RCF_{max} = 321{,}000g$) in an International B-60 ultracentrifuge, and the sedimentation patterns were obtained on an Isco gradient analyser. The ribosomes, washed with 1·0 M NH_4Cl, had been obtained as a byproduct in recovering DF from cells of *E. coli* MRE-600. The ribosomal pellet from the 1 M NH_4Cl solution was dissolved in 10 mM Tris-HCl (*p*H 7·8), 50 mM KCl, 10 mM magnesium acetate, 5 mM DTT, and 20 per cent glycerol, to an A_{260} of 500 units/ml. These ribosomes were stored up to 4 weeks at 4° C; and with the RNA of phage MS2 as messenger and with initiation factors added they incorporated 14 moles of ^{14}C-valine (about 1 mole of coat protein) per mole. This activity compares well with that of freshly made extracts (S-30) from log phase cells[14]. The purified F_3, provided by S. Sabol[13] as a powder lyophilized from NH_4HCO_3, was dissolved in 0·25 M Tris-HCl (*p*H 7·6), 1·0 mM DTT, and 7·5 per cent sucrose to 1 μg/μl.; dilute solutions (0·1 μg/μl.) were made with the same buffer.

In the cell, of course, the response to DF may well be enhanced by other factors: for example, the inhibition by Mg^{2+} can be antagonized by increased concentrations of KCl or of Tris (unpublished observations). Moreover, although 5 mM Mg^{2+} or more is required for optimal protein synthesis in an *in vitro* system with natural messenger, the free Mg^{2+} concentration in this system (and hence presumably in the cell) may be lowered substantially by the nucleotides and nucleic acid present in this system but not in our DF assay system. The ratio of bound to free DF in the cell is therefore likely to be even higher than the 8 : 1 calculated above.

With unpurified preparations of DF we[6] and Gonzalez *et al.*[16] have observed that dissociation is stimulated

* In the experiments of Ron *et al.*[2], in which the effect of low Mg^{2+} in the gradient was tested, some dissociation was observed with Mg^{2+} as high as 2 mM. In the present experiments the ribosomes were incubated at low Mg^{2+} and then analysed in a gradient containing 5 mM Mg^{2+}.

† In our earlier work[5,6] we had used unwashed runoff ribosomes to establish a physiologically significant interaction of DF with a natural component of the cell. But NH_4Cl-washed ribosomes have proved equally satisfactory for DF assays (see also refs. 13 and 17). Evidently this washing completely removes the ligands that protect complexed, polysomal ribosomes from dissociation by DF.

two-fold by 1·0 mM GTP or certain other nucleoside triphosphates, even with an equivalent amount of Mg^{2+} added. Others, however, have observed no effect of GTP with partially purified DF[17] or purified F_3 (ref. 13). With pure F_3, and with recent unpurified preparations, we now find that the stimulatory effect of GTP can be completely suppressed by an equivalent amount of Mg^{2+}. This effect may therefore be accounted for by chelation of Mg^{2+}. The 5 mM Mg^{2+} plus 1 mM GTP in our standard assay is thus equivalent to 4 mM Mg^{2+} alone.

Is F_3 the Only Dissociation Factor?

Although pure F_3 has DF activity and pure F_1 and F_2 have not, when a crude initiation factor preparation is fractionated on a DEAE–cellulose column by the procedure of Iwasaki *et al.*[9] the F_1 fraction (that which comes through unadsorbed) contains about 25 per cent of the total DF activity, the remainder being found in the F_3 cut[6,11]. But when the DEAE–cellulose fractionation was carried out as described by Sabol *et al.*[13] the entire DF activity was eluted at the position expected for F_3. It seems likely, therefore, that in the NH_4Cl extract of ribosomes, F_3 is the only protein with DF activity. Because it is a basic protein the variation in its adsorption on DEAE–cellulose could be accounted for by a dependence on association with anions.

Miall *et al.*[18], using a buffer with 6 M urea, found that all the DF activity passed through a DEAE–cellulose column, and they concluded that their final, purified DF might be F_1. We have found, however, that in the procedure of Sabol *et al.*[13] the DF activity is no longer retained by the column when the buffer contained 6 M urea. Thus the purification of DF by Miall *et al.* could have concentrated factor F_3, but because the product was less active than the F_3 of Sabol *et al.* and was reported to have a lower molecular weight (9,000 as against 21,200), it seems likely to have been a mixture of F_1 and F_3.

DF Content of Ribosomal Extracts

Our model[5] for the ribosome–polysome cycle requires the presence of a molecule of DF on every native 30S subunit to prevent spontaneous reassociation with a 50S subunit. Yet the 1 M NH_4Cl extract from 100 mg of ribosomal pellet (and thus from 10–20 mg of subunits) dissociates only 1 mg of runoff ribosomes in our standard assay[5]; and the low apparent yield is not the result of incomplete extraction, because re-extraction yields negligible activity (unpublished observations). But because the efficiency of the DF response in our standard assay is only about 5 per cent, the recovery of DF is consistent with the proposed model. (These data are not precise enough, however, to exclude the possibility that part of the "native" 30S peak may consist of immature or damaged subunits.)

The above calculation derives the content of F_3 (DF) in an extract from its activity. A similar content can be calculated from the data of Sabol *et al.*[13] on the recovery of F_3 as a protein, without assumptions concerning its activity. According to their Table 1, 3·4 kg of cells yielded 15 mg of pure F_3, with 19 per cent recovery, corresponding to 79 mg in the initial extract. Because *E. coli* cells yield about 40 mg of ribosomes per g, the extract would have been made from about 136 g of ribosomes. If each ribosome had yielded 1 molecule of F_3 the content in the extract would have been $(21{,}200/2{\cdot}6\times10^6)\times136$, or 1·1 g of F_3. The actual content (79 mg) is thus much too low to correspond to 1 molecule per ribosome, but it corresponds quite nicely to 1 molecule per native subunit.

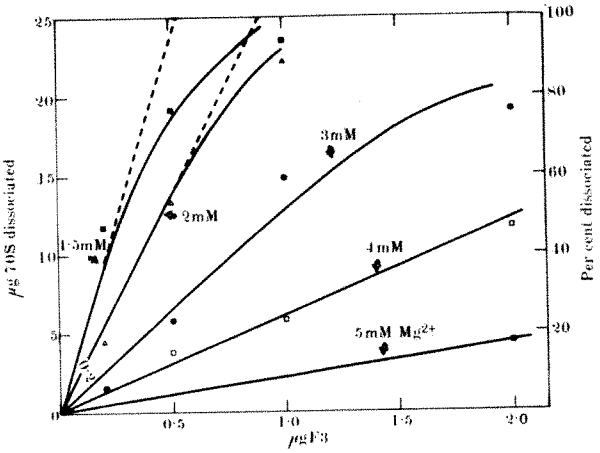

Fig. 3. Linearity of the dissociation response to increasing amounts of F_3 at various Mg^{2+} concentrations. The data are those of Fig. 2, with 25 μg of 70S ribosomes corresponding to 100 per cent.

This work was supported by research grants from the US National Institutes of Health, the US National Science Foundation, and the American Cancer Society. The technical assistance of Anita Blau is acknowledged.

Received August 24, 1970.

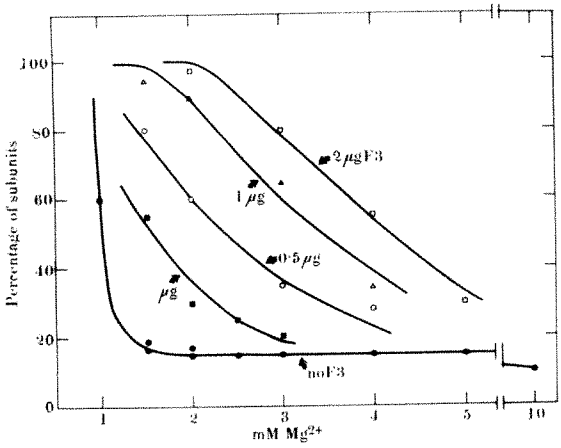

Fig. 2. Dissociation of 70S ribosomes by F_3 at various Mg^{2+} concentrations. The procedure was as in Fig. 1 except for variations in the concentrations of F_3 and magnesium acetate. The per cent dissociation was determined by cutting out and weighing a tracing of the peaks; the background level of dissociation, without added F_3, is not subtracted, and so 100 per cent represents dissociation by F_3 of 25 of the 30 μg of ribosomes present.

Novel Subunit in Secretory IgA

by

MICHAEL S. HALPERN

Virus Laboratory,
University of California,
Berkeley 94720

A new component, "J" (for joining), has been found in rabbit and human secretory IgA in addition to the S, α, and light chains already characterized. J has a molecular weight of approximately 23,000 and, by contrast with the S component, is disulphide-linked to the α chain. It is present in the dimer but not the monomer form of human IgA myelomas, and therefore seems to be responsible for the dimer structure characteristic of secretory IgA.

Secretory IgA possesses a polypeptide chain designated secretory or S component[1] which is not found in serum IgA[2]. This chain is known to be synthesized by epithelial acinar cells rather than the plasma cells responsible for light and heavy chain synthesis[2,3]. The two cell interaction required for secretory IgA synthesis has focused intense interest on the assembly of the IgA macromolecule.

Cebra and Small[4], working with rabbit colostral IgA, concluded that the light and heavy chains are assembled into two IgG-like monomeric units, and the S component is linked non-covalently to the molecule. Their data suggested that the S component is composed of two 25,000 molecular weight subunits linked by a disulphite bond. The occurrence of S subunits was deduced from electrophoretic studies which showed a fast-moving band migrating ahead of light chain in preparations of completely reduced and alkylated IgA. These conclusions are somewhat at variance with those of Tomasi and Bienenstock[5], who found that in human secretory IgA only a fraction of S component was non-covalently bound to the molecule, the majority being linked by disulphide bonds. In addition, the human S component could not be broken down into subunits following treatment with reducing agents. The discrepancies in the two studies were ascribed to species differences in the IgA.

The structural studies presented here were carried out on IgA isolated from rabbit and human colostrum. The rabbit IgA was purified by the method of Cebra and Robbins[6] and the human IgA by the method of Tomasi and Bienenstock[5]. The purity of the preparations was tested by immunoelectrophoresis against goat anti-rabbit whey and serum and goat anti-human serum. At a concentration of 10 mg/ml., the preparations exhibited no other precipitin arc than that corresponding to the respective IgAs.

As the first step in its fractionation, the rabbit IgA was treated with detergent to dissociate the non-covalently bound S component. The dissociation seemed to be complete, for no further S component was obtained on subsequent treatment with a combination of 8 M urea and detergent. The S component could then be separated by chromatography on a 'Sephadex G-200' column equilibrated with 0·05 M decyl sulphate or by electrophoresis on sodium dodecyl sulphate (SDS) polyacrylamide gels[7]. The latter results are illustrated in Fig. 1. The complex of covalently bound heavy and light chains barely penetrated the gel (Fig. 1*b*), while the S component migrated with a slightly lower mobility than bovine serum albumin (compare Fig. 1*b* with Fig. 1*a*). From a comparison of the positions of the S component and albumin, the S component seemed to have a molecular weight of approximately 70,000.

To determine its subunit structure, the isolated rabbit S component was completely reduced in the presence of 10 M urea and the resulting SH groups were alkylated with iodoacetamide. Subsequent electrophoresis on SDS gels revealed only a single component (Fig. 1*d*) which had essentially the same molecular weight as the untreated S (Fig. 1*c*). Furthermore, when the reduced and alkylated S component was chromatographed on 'Sephadex G-200' equilibrated with decyl detergent (Fig. 2), the protein emerged as a single peak slightly behind the elution volume of non-reduced S. The absence of smaller molecular weight material eliminated the possibility that the S component is composed of subunits. The slight difference in the elution volume of reduced S, corresponding to a change in molecular weight from 70,000 to 64,000, suggested that its conformation was altered during the reduction of the disulphide bonds.

Similar methods were applied to investigate the subunit structure of the covalently bonded complex remaining after the dissociation of the S component. When the completely reduced and alkylated material was electrophoresed on SDS gels or subjected to chromatography on 'Sephadex G-200' only two fractions were obtained which exhibited the behaviour typical of α and light chains. When the reduced material was electrophoresed on an alkaline urea gel[8], however, a densely staining component was seen migrating in the leading edge of the light chain region (Fig. 3*b*). The same densely staining component was observed when the isolated light chain fraction, but not when the isolated heavy chain fraction was subjected

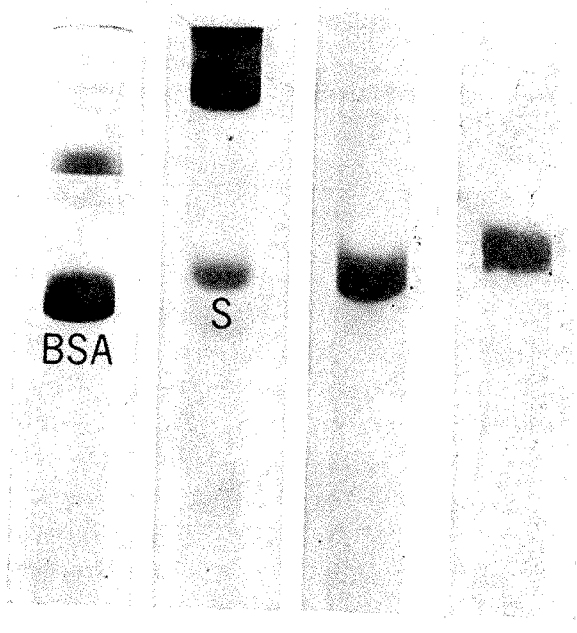

Fig. 1. Electrophoretic patterns obtained on 5 per cent polyacrylamide gels *p*H 8·1 with 0·1 per cent SDS. Electrophoresis for 3 h at 12 V/cm. *a*, Bovine serum albumin (BSA); *b*, rabbit secretory IgA; *c*, rabbit S component; *d*, rabbit S component reduced in the presence of 10 M urea with 0·15 M dithiothreitol and alkylated with 0·45 M iodoacetamide.

to electrophoresis on alkaline gels (Fig. 3*d*). Thus the co-chromatography with the light chain indicated that the fast-moving component had a molecular weight of approximately 23,000.

This fast-moving component had previously been shown to be peculiar to secretory IgA[9] and was thought[3] to represent the subunit of S. Such an interpretation is ruled out by the findings reported here that S has a single chain structure and that the fast-moving component is present in IgA freed of S. Two alternative explanations are consistent with these findings: either the fast moving component represents a light chain type peculiar to IgA, or it represents an additional subunit in the IgA macromolecule. (From now on, the letter "J" will be used to designate the fast-moving component.)

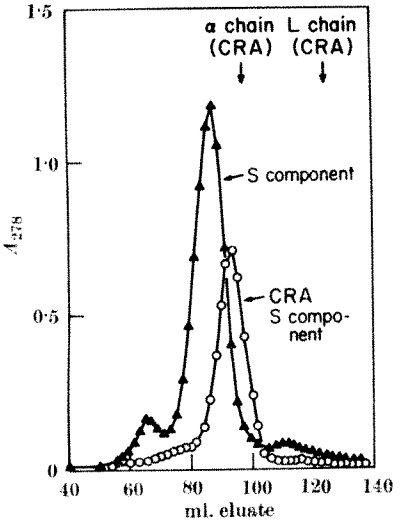

Fig. 2. Chromatography on 'Sephadex G-200' equilibrated with decyl detergent of S component and S component (CRA) after complete reduction and alkylation (10 M urea, 1 M mercaptoethanol and 1·05 M iodoacetic acid).

Evidence suggesting that J is not a light chain was provided by amino-acid analyses of the material eluting at the light chain position when completely reduced and alkylated IgA was chromatographed on 'Sephadex G-200'. The average composition of these fractions was compared with the composition of IgC light chains isolated from the same animals and prepared in identical conditions. As shown in columns 1 and 2 of Table 1, the composition

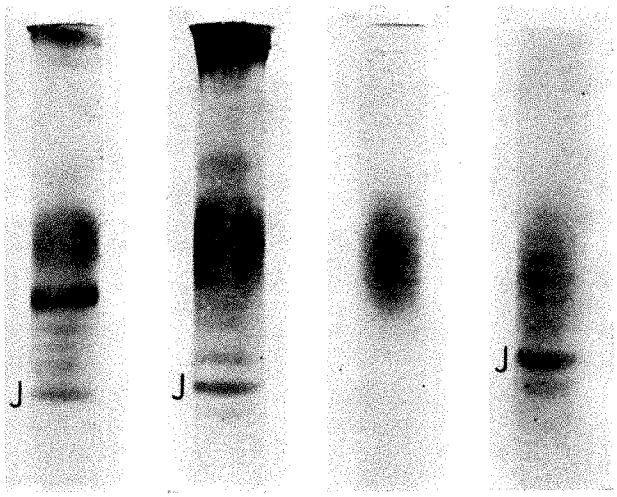

Fig. 3. Electrophoretic patterns obtained on 4 per cent polyacrylamide gels pH 8·7 with 8 M urea. Electrophoresis for 2 h at 40 V/cm. *a*, Rabbit secretory IgA reduced in the presence of 10 M urea with 0·15 M dithiothreitol and alkylated with 0·45 M iodoacetamide; *b*, rabbit IgA freed of S component treated as in *a*; *c*, material which eluted in the light chain position of a 'Sephadex G-200' chromatogram of mildly reduced and alkylated rabbit secretory IgA (0·1 M mercaptoethanol and 0·105 M iodoacetamide); *d*, material which eluted in the light chain position after complete reduction and alkylation of aggregated material eluted in preparations of mildly reduced and alkylated rabbit IgA (10 M urea, 1 M mercaptoethanol and 1·05 M iodoacetamide).

of the IgA light chain fraction differed considerably from that of the IgG. Statistical analyses showed that the content of seven amino-acids, arginine, aspartic acid, serine, glycine, alanine, valine, and isoleucine, was different in the IgA and IgG light chain fraction ($P < 0{\cdot}01$). Moreover, the IgA light chain fraction always contained residual glucosamine while the IgG light chains contained none.

The disulphide bond(s) linking J chain were found to be less susceptible to reductive cleavage than most of the light–heavy interchain disulphide bonds. When secretory IgA was mildly reduced in conditions which freed approximately 65 per cent of the total light chain present, only light chains of IgG-like composition and electrophoretic behaviour were obtained (Table 1, column 4, and Fig. 3*c*). When the remaining 35 per cent of the light chain bound to heavy chain was released by complete reduction and alkylation, J chain appeared in the fraction eluting at the light chain position. Furthermore, J comprised a relatively greater proportion of the total material in the fraction as shown by the denser staining of the anodal band (compare Fig. 3*d* with Fig. 3*a*) and by the more anomalous composition of the mixture (Table 1, column 6). The finding that a high percentage of normal light chain could be separated from the J chain suggested that J is linked to heavy chain.

When these investigations were extended to human colostral IgA, evidence was obtained for a comparable J chain. The characteristic fast-moving bands were found to be present in the light chain fraction, indicating that human J also had a molecular weight in the order of 23,000. The electrophoretic mobility of the bands was similar to that exhibited by the rabbit J, but the human J could be resolved more easily because of the slower mobility of the human light chains. These data are illustrated in Fig. 4, in which the banding of the light chain fractions from completely reduced and alkylated human IgA and human IgG are compared (compare Figs. 4*a* and *b*). Furthermore, the average compositions of the human IgA light chain fractions differed significantly from the control IgG fractions and many of the differences were in the same direction as those observed in the analyses of the rabbit material.

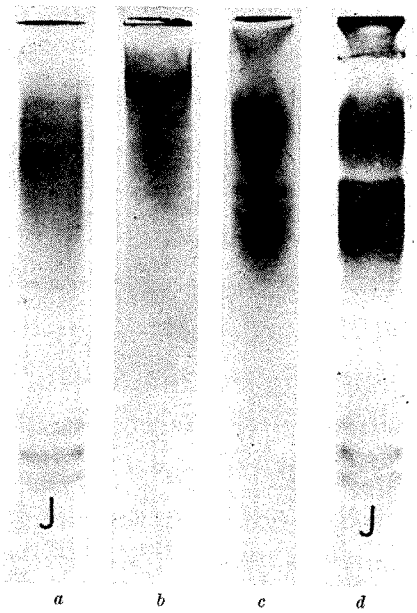

Fig. 4. Electrophoretic patterns obtained on 4 per cent polyacrylamide gels *p*H 8·7 with 8 M urea. Electrophoresis for 2 h at 40 V/cm. *a*, Light chain fraction from totally reduced and alkylated human secretory IgA; *b*, completely reduced and alkylated human IgG; *c*, completely reduced and alkylated monomer from a $\gamma A_2(\lambda)$ myeloma; *d*, completely reduced and alkylated dimer from the same myeloma.

Although these studies of rabbit and human secretory IgA supported the interpretation that J is a novel subunit, the data were not sufficient to eliminate the possibility that J is a special light chain more resistant to reductive cleavage than most light chains. To obtain more conclusive evidence, investigations were carried out on human IgA myelomas in which both monomer and dimer forms were produced (myeloma proteins purified from human serum kindly provided by Drs Hugh Fudenberg, Al Levin and Richard Pink). Three pairs of proteins were studied, one pair of the γA_1 subclass, containing $\varkappa$ light chains, a second of the same subclass but containing λ light chains, and a third of the γA_2 subclass containing λ chains. When the protein pairs were completely reduced and alkylated and electrophoresed on alkaline urea gels, fast moving bands were found to be present in all the dimers but absent from all the monomers. The typical patterns obtained are illustrated in Figs. 4*c* and *d* by the $\gamma A_2(\lambda)$ set. It may be seen that the J from the myeloma dimer had the same mobility and charge heterogeneity as the human colostral J (compare Figs. 4*d* and *a*). At the same time the banding of the heavy and light chains was identical in the monomer and dimer, indicating that one clone was synthesizing both forms of the IgA. Any one clone of plasma cells is known to produce only a single light chain, so these results demonstrate that J is a novel subunit.

In the case of the myeloma IgA, J would appear to be synthesized in the same plasma cell as the heavy and light chains and to function by linking the monomeric units. Rabbit colostral IgA has also been shown to be secreted from the plasma cell as a dimer[10], so a similar process presumably occurs in the synthesis of normal secretory IgA. The mechanism of J is obtained and its molar ratio in the dimer IgA determined.

The role of J in the final assembly of the dimer and the S component is intriguing. J may provide the binding site for S, either directly through the contribution of groups to the site, or indirectly through an induced conformational change in the α chains. J may further provide the recognition signal for the interaction between the plasma cell synthesizing the J–dimer complex and the epithelial cell synthesizing the S component. Studies are in progress to evaluate these possibilities.

This investigation was supported by a US Public Health Service grant from the National Institute of Allergy and Infectious Diseases, and by a training grant from the National Cancer Institute.

In vitro Combination of Human and Bovine Free Secretory Component with IgA of Various Species

by
JEAN-PIERRE MACH
Institut de Biochimie,
Université de Lausanne,
Switzerland

The free form of the secretory component usually associated with secretory IgA can be isolated from human and bovine milk. These free secretory components of different origin combine *in vitro* with human polymeric myeloma IgA, with mouse myeloma IgA, and with the serum IgA of nine different mammalian species.

Since the secretory component (SC) has been identified as a part of the secretory IgA (SIgA) and shown to be detachable from the IgA molecule in certain conditions[1–5], many attempts have been made to recombine the two separated parts of the SIgA *in vitro*[6,7]. Most of these experiments were done with an SC cleaved from SIgA by reduction and alkylation, and no study of the binding involved in this recombination has been reported. Combination of the free form of the secretory component with an IgA lacking SC would represent a test of greater functional significance. Free secretory component (FSC) is known to be present in human colostrum[4,5,8] and an analogous protein has been identified in bovine, ovine and caprine secretions[9–11]. This study deals with the combination of purified human and bovine FSC with polymeric human myeloma IgA (Fig. 2) and with IgA from the sera of nine different mammalian species (Fig. 3 and Table 1).

Purification of FSC from Human and Bovine Milk

This purification was based on the original observation that these two components are not retained by DEAE-

cellulose equilibrated with 0·01 M phosphate buffer (*p*H 7·4). The starting materials were 5th–10th day maternal milk and mature cow milk from which the fats and the casein had been removed by centrifugation at 45,000*g* for 1 h. The proteins were precipitated with 50 per cent saturated $(NH_4)_2SO_2$ at room temperature. The precipitation was performed twice in order to remove most of the lactoferrin remaining in the supernatant. The precipitate was redissolved, dialysed against 0·01 M phosphate buffer (*p*H 7·4) and applied to a DEAE-cellulose column equilibrated with the same buffer. In these conditions the secretory components were not retained by DEAE-cellulose and were obtained contaminated only with small amounts of IgG. These fractions were further purified by gel filtration on 'Sephadex G-200' and preparative ultracentrifugation on a linear 5 per cent to 20 per cent sucrose density gradient (45,000 r.p.m. for 15 h at 4° C in a Beckmann Spinco model L2.65 B ultracentrifuge).

The purified proteins gave only one line on immunoelectrophoresis with a polyvalent antiserum (Fig. 1*a*, *c*). When revealed in whole colostrum by anti-SIgA antiserum the human and the bovine FSC gave a β_2-line fusing partially with SIgA (Fig. 1*b*, *d*). Tested by double diffusion with an antiserum against SIgA, purified human and bovine FSC showed a partial identity with human and bovine SIgA respectively and no common antigenicity with human myeloma IgA and bovine serum IgA (Fig. 1*e*, *f*). Their molecular weights were determined by electrophoresis in polyacrylamide gels containing sodium dodecyl sulphate (SDS) according to Weber and Osborn[12]. The values obtained were 85,000 for human FSC and 75,000 for bovine FSC (Fig. 1*g*). These results are consistent with those of Newcomb *et al.*[4], who reported a molecular weight of 76,000 for human SC.

Combination of FSC with Human Myeloma IgA

One hundred μg of each of the above purified FSC, labelled with ^{125}I by the chloramine T method[13], were incubated for 1 h at 37° C (in 0·5 ml. of 0·14 M NaCl adjusted to *p*H 7·4 with 0·01 phosphate buffer) either with 5 mg of purified human IgG or with 2 mg of purified human myeloma IgA of polymeric form. After incubation, these proteins were applied to a 'Sephadex G-200' column. When incubated with IgG, 96 per cent of the labelled FSC protein was eluted just after the 7S peak (Fig. 2*a*), indicating that it remained in its free form. On the other hand, when incubated with myeloma IgA, 86 per cent of the labelled FSC was eluted with the IgA protein in the exclusion volume of the 'Sephadex G-200' column (Fig. 2*c*), suggesting that most of the labelled FSC had been bound to the polymeric IgA. Similar results were obtained by ultracentrifugation of the incubated protein on sucrose density gradients.

Guinea-pig	26	+	?	0	Rabbit anti-guinea-pig SIgA§
Mouse	27	+	Traces	0	Rabbit anti-mouse myeloma IgA‖

* Determined by the intensity of the lines on autoradiography of immunoelectrophoresis technically identical to the ones shown in Fig. 2.

† The bovine, ovine and caprine IgA were previously identified and shown to be homologous to human IgA[10,11,17].

‡ Similar cross-reactions of antiserum against human IgA with the IgA of these species have been reported[17].

§ This antiserum was obtained from Dr A. Asofsky, of NIH, Bethesda, USA. It did not react with the human and bovine FSC preparations used in the combining experiment.

‖ This antiserum was obtained from Dr H. Jaquet, Institut de Biochimie, Lausanne, Switzerland[24].

Binding to IgA was confirmed by autoradiography taken from immunoelectrophoresis[14] and single radial diffusion analysis[15] of the fractions eluted from the 'Sephadex' column, using an antiserum monospecific for IgA. This antiserum did not react either with the small peak of FSC remaining in the free form or with the whole labelled FSC preparation. Bovine and human FSC were bound to human IgA equally well. In order to show that polymeric myeloma IgA was not binding any protein nonspecifically, purified human serum albumin (HSA) was labelled and tested for combination with myeloma IgA in an identical experiment. There was no *in vitro* combination between IgA and HSA. HSA was chosen for this test because a small amount of it has been found attached to myeloma IgA or serum IgA[16,17]. The combination of FSC was confirmed with polymeric myeloma IgA obtained from five different patients. These IgA myeloma preparations were purified by DEAE-

cellulose chromatography and the polymeric form selected by filtration on 'Sephadex G-200'. When tested with polyvalent antiserum, they gave only one line on immunoelectrophoresis. Examination by analytical ultracentrifugation showed them to be heterogeneous and composed of several polymers with sedimentation coefficients ranging from 10S to 15S.

When a 7S IgA fraction (selected by 'Sephadex G-200' filtration from a serum containing a myeloma IgA mostly of monomeric form) was incubated with FSC in an identical experiment, no combination occurred. Thus the polymeric form of IgA was necessary for the *in vitro* combination. This is in agreement with the present concept of the *in vivo* combination, which is based on the recent observation that rabbit as well as human SIgA have symmetrical light chains and should therefore be synthesized by a single plasmocyte[18–20]. This synthesis of IgA dimers by single plasmocytes has to occur before combination with FSC.

Another combination test was done with 7S myeloma IgA polymerized by reduction followed by reoxidation in acetate buffer at *p*H 5, according to the method of Abel and Grey[21]. Polymerization of 40 per cent of the 7S IgA was obtained but the FSC did not combine with it. This shows that the artificially prepared polymers are not identical with the native polymers. The details of these experiments have been reported at the fourth Immunopathology Symposium[22]. Heat aggregated IgG did not show any more binding ability than did 7S IgG. On the other hand, purified IgM obtained from patients with Waldenström's disease was able to bind FSC as well as polymeric myeloma IgA. Whether or not this binding is due to polymers of IgM or to the monomeric form is under investigation. The *in vitro* combination of FSC with purified IgM agrees with the recent observation of Thompson, who demonstrated the presence of secretory antigenic determinants on the IgM of patients with IgA deficiency[23].

Denaturation of IgA combined with FSC

The strength of the binding between FSC and IgA was tested by exposing the combined proteins excluded from 'Sephadex G-200' (Fig. 2*c*) to different denaturing agents for 6 h at room temperature and then chromatographing the proteins on a 'Sephadex G-200' column equilibrated with the same denaturing agent. The results show that when treated with 0·5 M propionic acid, the combined proteins remained almost entirely bound (Fig. 2*d*); when treated with 6 M guanidine, 21 per cent of the labelled SC was detached (Fig. 2*e*). This last result corresponds to what has been observed when native human SIgA was treated with 6 M guanidine[6] and suggests that the *in vitro* combination is similar to the one which occurs *in vivo*. The bovine FSC combined with human myeloma IgA gave similar results when tested with denaturing agents. Preliminary results indicate that the binding of FSC with IgM is as resistant to denaturation as the binding with IgA.

Reduction and Alkylation

The binding involved in this *in vitro* combination was further studied by reduction and alkylation. When

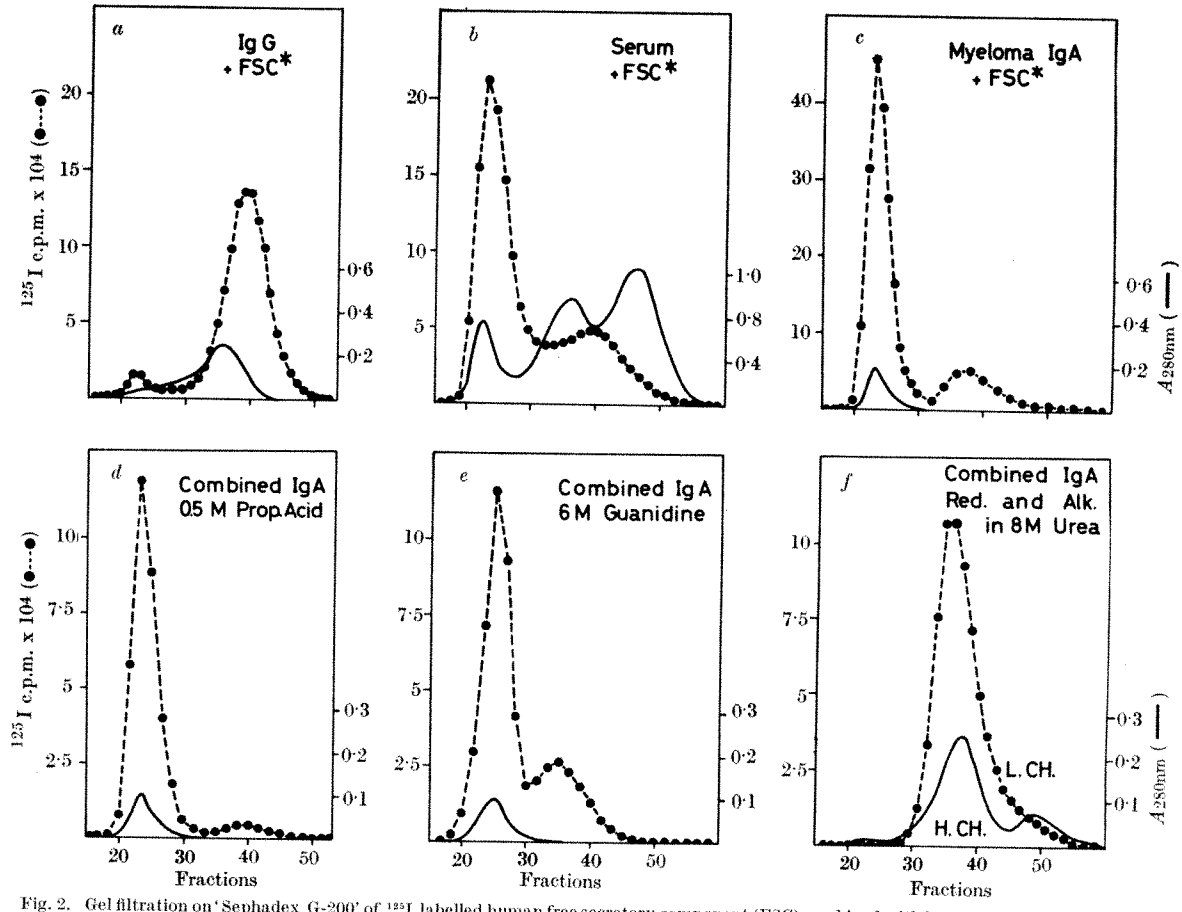

Fig. 2. Gel filtration on 'Sephadex G-200' of ^{125}I labelled human free secretory component (FSC) combined with human serum and polymeric myeloma IgA. The dotted line represents the ^{125}I counts per minute $\times 10^4$ (scale on the left of the graphs); the full line, the absorbance of the proteins at 280 nm (scale on the right). *a*, Control showing unbound FSC (incubated with human IgG as indicated in the text) eluted after the 7S IgG peak; *b*, elution pattern of FSC after incubation with normal human serum; *c*, elution pattern of FSC after incubation with human polymeric myeloma IgA; *d–f*, filtration of polymeric myeloma IgA combined with FSC (taken from the first peak of *c*) in *d*, after denaturation by 0·5 M propionic acid, in *e*, after denaturation by 6 M guanidine, in *f*, after reduction and alkylation in 8 M urea as indicated in the text. In *a–c* the 'Sephadex G-200' was equilibrated with 0·05 M Tris–0·2 M NaCl solution adjusted to *p*H 8 by HCl; in *d–f* with the above-mentioned denaturing agents. In *f*, H.CH = heavy chain and L.CH = light chain.

the "combined IgA" (first peak of Fig. 2*c*) was only partially reduced and alkylated, without the use of denaturing agents, the two proteins were separated. The IgA was depolymerized and eluted from 'Sephadex G-200' as 7S IgA, before the labelled SC which was eluted as the native FSC. This separation by partial reduction and alkylation, contrasting with the resistance to denaturing agents, seems to indicate that disulphide bridges are involved in the *in vitro* combination. (The reduction was performed by 0·02 M dithiothreitol in Tris 0·05 M–NaCl 0·20 M solution adjusted to *p*H 8 by HCl, for 1 h at 37° C and the alkylation by 0·04 iodoacetamide for 1 h at 37° C, the *p*H maintained at 8 by the addition of solid Tris.) When the "combined IgA" was completely reduced and alkylated using the same reagents in the presence of 8 M urea, the IgA chains were dissociated but the labelled SC remained apparently intact (Fig. 2*f*), suggesting that it is made of a single polypeptide chain. The complete reduction and alkylation of unbound human and bovine FSC gave identical results.

FSC combines with Serum IgA of Different Species

One hundred μg of labelled FSC was incubated with 1 ml. of serum for 1 h at 37° C and applied to a 'Sephadex G-200' column. The elution pattern of human serum combined with human FSC after filtration on 'Sephadex G-200' is shown in Fig. 2*b*. About 78 per cent of the labelled protein was eluted with the exclusion volume, suggesting a combination of FSC with a rather large protein. When human FSC was incubated in identical conditions with the serum of a completely agammaglobulinaemic patient or with human cord serum (which contains IgG but neither IgA nor IgM), less than 5 per cent of the labelled material was eluted in the exclusion volume and 95 per cent remained unbound, giving a similar elution pattern to that of the control with IgG (Fig. 2*a*). These controls indicate that, in the case of the normal serum, the combination must have occurred with IgA or IgM. Single radial diffusion and autoradiography of the eluted fractions, using antisera monospecific for IgA, IgM and IgG, showed that the FSC combined mostly with IgA. The preferential affinity for IgA was further demonstrated by immunoelectrophoresis and autoradiography of the combined proteins as shown in Fig. 3*a*. Bovine FSC was combined with human serum IgA as well as human FSC (Fig. 3*b*). In the light of this observation combinations with the sera of other species were tried. Table 1 summarizes the results obtained with the serum of nine mammalian species. It indicates the percentage of labelled FSC, either human or bovine (average from four determinations), combined with pooled normal serum from the species tested, the relative amount of FSC attached to IgA, IgM and IgG, roughly evaluated from the intensity of the lines on autoradiography of immunoelectrophoresis, and the antiserum used for precipitation of the protein homologous to human IgA (similar cross-reacting antisera were used to reveal IgG and IgM). These results show that in the nine species tested, FSC was bound mostly to IgA. In a few species, namely the ruminants which have a low level of serum IgA[10,11], FSC was also attached to IgM (Fig. 3*c*, *d*). In no species did the FSC bind significantly to IgG. A particular case was the sera of mice with IgA myeloma (either C3H × 5647 or BALB/c MPC-1)[25,26]. In these sera 70 per cent of the FSC preparations were bound specifically with the mouse IgA paraprotein (Fig. 3*e*). Mouse myeloma IgA is known to have many common properties with human myeloma IgA, the same size heterogeneity, a high carbohydrate content[27] and a similar C-terminal tripeptide[28]. Now it is shown that it binds equally well human FSC.

In conclusion, the similar ability of the serum IgA of all nine species tested to bind FSC suggests that this is a property of the IgA of all mammals. Only two non-mammalian species, chicken and duck, were tested for

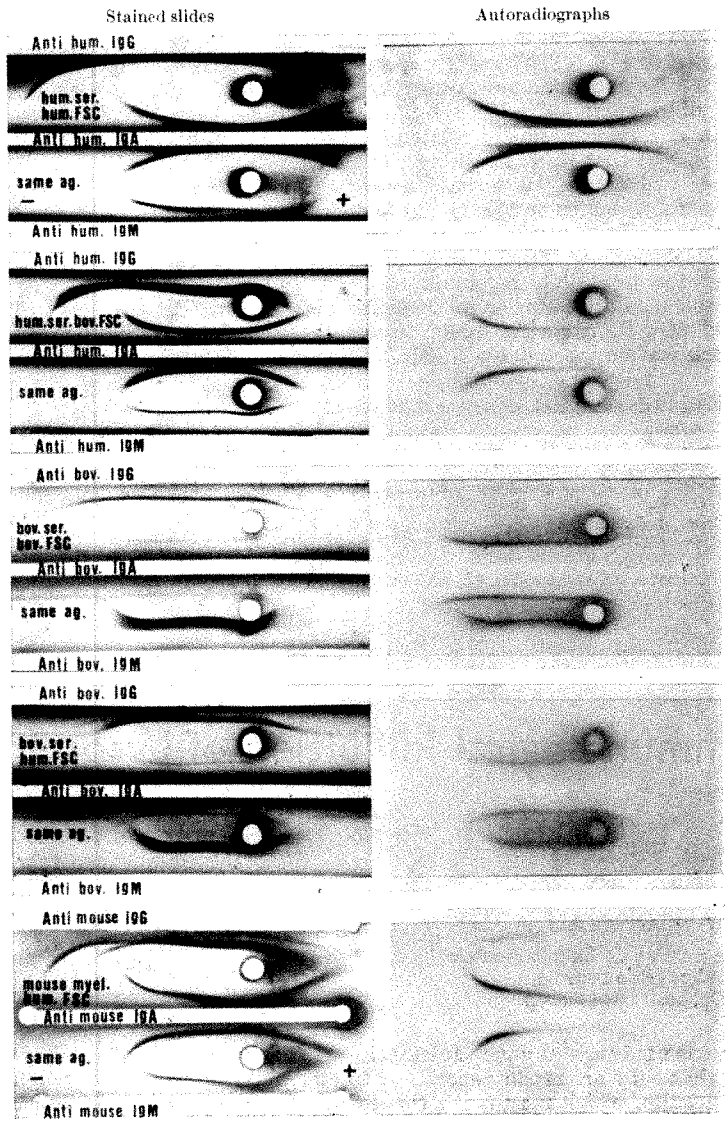

Fig. 3. Immunoelectrophoresis and autoradiographs showing the combination of human and bovine labelled free secretory component (FSC) with human and bovine serum IgA or IgM and with mouse myeloma IgA (C3H ×5647)[25]. Antisera: pig and rabbit antisera, monospecific for human bovine or mouse IgG (upper trough), IgA (middle trough) and IgM (lower trough), were used as indicated in the pictures. In *c* and *d* upper trough the antiserum is monospecific against bovine IgH_1 (IgG_2 was tested on other slides and found also unable to bind FSC). (Only one antiserum, against mouse IgG applied in the upper trough of *e*, was not monospecific and revealed partially the myeloma IgA appearing in autoradiograph as a short labelled line.) Antigens: combined fractions—first radioactive peak from 'Sephadex G-200' plus part of the 7S IgG peak (the second radioactive peak of unbound FSC was discarded), of human, bovine and mouse (with IgA myeloma) serum incubated with either human or bovine labelled FSC, were applied to the wells as indicated in the picture. The autoradiographs, shown on the right, were obtained by exposing photographic film (Kodak Royal Pan), for 24 h in the dark, to the immunoelectrophoretic slides shown on the left of the picture.

combination and their sera exhibited a very low binding ability for human FSC (6 per cent and 3 per cent respectively). The fact that, in addition to IgA, the IgM of some mammals was able to bind FSC *in vitro* should be emphasized in the light of the hypothesis that IgA is phylogenetically related to IgM[29]. Finally, it is suggested that this combining test should be standardized and used as one of the criteria for the identification of immunoglobulins in newly studied species.

I thank Professor H. Isliker, Drs D. S. Rowe, H. Jaquet, F. Dolder and C. S. Henney for advice and suggestions, and for providing myeloma proteins and antisera. I thank also Miss Marianne Dysli for technical assistance, and Mrs R. Allan for reviewing the manuscript. This work was supported by Nestlé SA, Vevey, Switzerland.

Immunological Inhibition of Lysosome Function

by
PAUL TULKENS
ANDRÉ TROUET
FRANÇOIS VAN HOOF
Laboratoire de Chimie Physiologique,
Université de Louvain,
6 Dekenstraat, Louvain

Antibodies directed against soluble components from purified liver lysosomes are taken up by fibroblasts and to impair lysosomal function. As a result, lysosomal hydrolases are inhibited, the uptake and digestion of foreign protein are impaired and there is a marked increase in the size and number of lysosome-like cytoplasmic bodies —resembling the condition seen in many storage diseases.

Lysosomes are unique among intracellular organelles in that they are readily accessible to extracellular macromolecules, which may reach them through the operation of endocytosis followed by fusion of the endocytic vacuole with a lysosome[1]. In the past, this property has been exploited successfully for extending the digestive capacity of lysosomes to a new substrate (sucrose) by means of the appropriate enzyme (invertase)[2]. The opposite end—curtailment of lysosomal digestion—has been pursued in the present experiments, in which cells were exposed to antibodies inhibitory to their lysosomal hydrolases. We describe here the first results of these experiments which provide evidence, both biochemical and morphological, that the antibodies are taken up within the lysosomes and cause a severe impairment of their functioning. As a test system, we used rat fibroblasts obtained by trypsinization from 18–20 day old embryos, and cultured at 37° C in a modified Eagle–Dulbecco medium[3] containing 10 per cent of heat-inactivated calf serum. The cultures used in our experiments were essentially in the stationary phase, and contained about 0·15 mg fibroblast protein per ml. of medium. For harvesting, the cells were detached with 0·02 M EDTA, collected by centrifugation, and washed several times with ice-cold 0·25 M sucrose.

Preparation and Properties of γ-Globulin

Immunoglobulins directed against the soluble components of rat liver lysosomes (anti-LS globulins) were prepared essentially as described by A. T. In brief, lysosomes were separated by flotation from the livers of rats injected with Triton WR-1339, ruptured by dialysis against 1 mM sodium bicarbonate and divided by high speed centrifugation into a soluble and an insoluble fraction. The soluble fraction, containing the bulk of the lysosomal hydrolases, was used for the immunization of rabbits. γ-Globulins were purified from the antisera by precipitation with 50 per cent ammonium sulphate, followed by chromatography on DEAE-cellulose with 0·08 M Tris-HCl buffer (*p*H 7·4). Non-immune rabbit sera were processed identically for the preparation of control γ-globulins. γ-Globulins were conjugated with fluorescein according to McKinney *et al.*[5], before the chromatographic step which was then performed with phosphate buffer (*p*H 6·3), the fraction eluting between 0·05 and 0·10 M phosphate being retained.

It has been shown by A. T.[4] that anti-LS globulins inhibit several acid hydrolases, not only of rat liver but also of rat bone and fibroblasts. Sera from control rabbits or from rabbits immunized against other subcellular fractions, including the insoluble lysosomal subfraction, had little or no effect. Fig. 1 illustrates some inhibitory effects of the anti-LS globulins used in the present work. The strong inhibition of cathepsin D, also observed by Weston *et al.*[8] with an antiserum against the purified protease, and that of acid deoxyribonuclease are particularly noteworthy, in agreement with the general finding that immunological inhibition of enzymes increases with the molecular size of their substrates[9]. In view of the importance of the hydrolases acting on macromolecules as initiators of digestion, it is likely that the anti-LS globulins are capable also of inhibiting strongly the breakdown of many of the complex materials that are the natural substrates of lysosomal digestion.

Uptake and Processing by Fibroblasts

Fibroblasts were cultured for 30 h in a medium containing 0·1 mg fluorescein-labelled control γ-globulins per ml. They were harvested, washed thoroughly, dissolved in 0·03 M NaOH containing 0·65 per cent sodium deoxycholate, and analysed fluorometrically at 520 nm, with an excitation wavelength of 480 nm, in a Zeiss ZFM 4C spectrofluorometer. Their average content of fluorescent material corresponded to 8·6 μg of labelled globulins per mg of protein. Examination of the cells in the fluorescence microscope showed the label to be concentrated within cytoplasmic granules (Fig. 2). The nature of these granules was investigated by isopycnic density gradient centrifugation. For this purpose, a homogenate of fibroblasts exposed for 30 h to fluorescein-labelled normal γ-globulins was prepared in 0·25 M sucrose and freed of nuclei by centrifugation for 10 min at 600*g*. The resulting cytoplasmic extract (10 ml.) was layered over a 32 ml. linear sucrose gradient (density 1·10–1·25), itself resting on a 6 ml. cushion of density 1·34, in the automatic zonal rotor of Beaufay[10]. After centrifugation for 3 h at 35,000 r.p.m., which sufficed to bring most particles practically to their equilibrium position in the gradient, the contents of the rotor were collected into thirteen separate fractions, which were assayed for various enzymes and for fluorescent material. The average density of each fraction was also measured, so that the results could be represented in the form of density distribution histograms of each component[11]. Fibroblast lysosomes, as detected by three acid hydrolases, are distinctly denser than are the other cytoplasmic particles identified by catalase (peroxisomes ?), cytochrome oxidase (mitochondria), and inosine diphosphatase (microsomes ?) (Fig. 3). The fluorescent material clearly follows the distribution of acid hydrolases, and is largely concentrated, together with these enzymes, in a region of the gradient practically free of the other marker enzymes.

Fig. 2. Fluorescence micrograph of fibroblasts cultured for 30 h in the presence of fluorescein-labelled normal γ-globulins (×1,400; excitation wavelength 420 nm). Cells incubated with unlabelled globulins showed no detectable fluorescence.

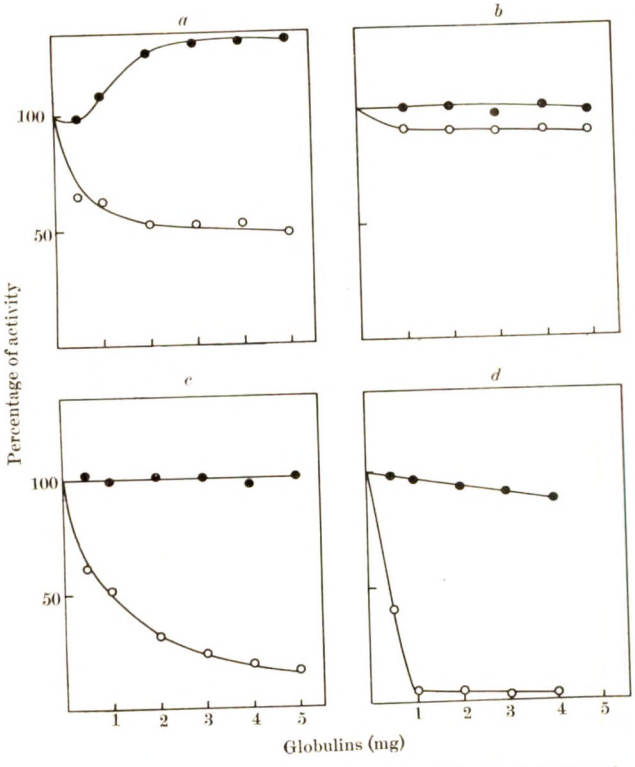

Fig. 1. Immunological inhibition *in vitro* of fibroblast lysosomal enzymes. Cultured cells were homogenized in 0·25 M sucrose with a Dounce homogenizer and then frozen and thawed several times. Amounts of homogenate containing 0·2 mg of protein were preincubated for 1 h at 37° C with the quantities of γ-globulins indicated in the abscissa, and then assayed for (*a*) β-N-acetyl-glucosaminidase[6], (*b*) acid β-glycerophosphatase[7], (*c*) acid deoxyribonuclease[7], and (*d*) cathepsin D[7] (the latter enzyme at *p*H 5·0). The enzymatic activities were measured in the absence of 'Triton X-100'. ●, Control globulins; ○, anti-LS globulins.

In another experiment, fibroblasts were kept for 4 days in a medium containing 0·1 mg of fluorescein-labelled control γ-globulins and 0·3 mg of unlabelled control γ-globulins per ml. At the end of the incubation, the medium was collected and fractionated on a column of 'Sephadex G-50' with 0·15 M NaCl–2 mM phosphate buffer (*p*H 7·4). The fractions were analysed by fluorometry. The cells were disrupted by freezing and thawing and treated with 0·1 per cent 'Triton X-100'. The supernatant recovered from this suspension by centrifugation at high speed, which contained all the intracellular fluorescent material, was also fractionated on 'Sephadex G-50' for fluorometric analysis. 2 per cent of the total fluorescent material was intracellular, 98 per cent extracellular (Fig. 4). Furthermore, 18 per cent of the intracellular and 36 per cent of the extracellular material were retarded on the column. In contrast the fluorescent γ-globulins, when incubated for the same length of time at 37° C with medium alone or with cell-free medium collected from a 4 day old culture, came out entirely with the void volume.

It seems from these results that fibroblasts take up fluorescein-labelled γ-globulins from the medium, break them down, and return conjugated fragments of the protein molecule to the medium. In all likelihood, this traffic takes place according to the generally accepted scheme of endocytosis and lysosomal digestion[1], which involves pinocytosis of the proteins, fusion of the pinocytic vacuole with a lysosome, and digestion of the proteins within the resulting secondary lysosome. The products of digestion are believed to diffuse or be transported across the lysosomal membrane, and to be metabolized in the cytoplasm. How the fluorescein-labelled fragments reach the extracellular medium in the present case, whether by diffusion or by some more specific excretion mechanism, is not known.

Effects of Anti-LS γ-Globulins on Fibroblasts

Fibroblasts were maintained for 4 days in the presence of 0·5 mg/ml. of either anti-LS globulins or control rabbit

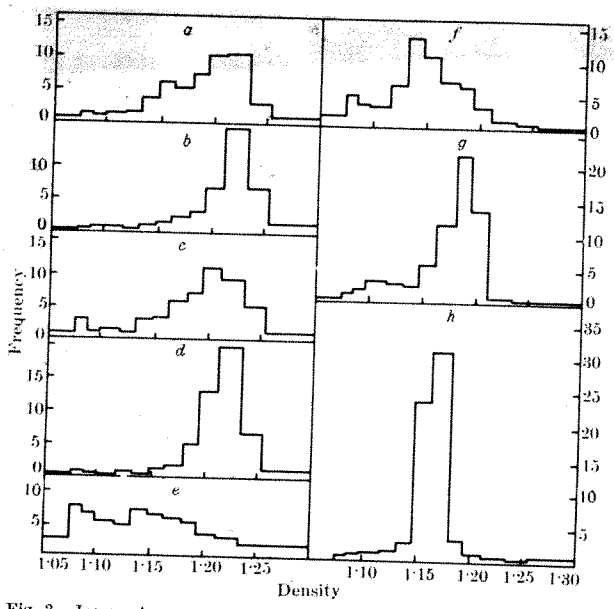

Fig. 3. Isopycnic centrifugation of a cytoplasmic extract (post-nuclear supernatant) obtained from fibroblasts cultured for 30 h in the presence of fluorescein-labelled control γ-globulins (0·1 mg/ml.). Fractions are analysed for (*e*) proteins[12], (*h*) cytochrome oxidase[7], (*g*) catalase[13], (*f*) inosine diphosphatase[14], (*a*) acid phosphatase[7], (*b*) β-N-acetyl-glucosaminidase[6], (*c*) cathepsin D[7] and (*d*) fluorescein labelled γ-globulins (or labelled γ-globulin fragments).

γ-globulins. The cells were then harvested, washed carefully, homogenized, and assayed for various enzymes. The activities of the cells exposed to the anti-LS globulins, expressed in terms of those of the control preparation, were 98 per cent for cytochrome oxidase and catalase, 82 per cent for acid phosphatase, 76 per cent for β-N-acetyl-glucosaminidase, 73 per cent for acid deoxyribonuclease, and 49 per cent for cathepsin D. The decrease in activity of the hydrolases parallels in relative magnitude that observed in a homogenate preincubated with anti-LS globulins (Fig. 1). This suggests that we are dealing, as in the latter case, with an immunological inhibition of the enzymes. But whereas some 0·3 to 0·4 mg of anti-LS globulins had to be added *in vitro* to 0·2 mg of fibroblast protein to produce the degree of enzyme inhibition observed in the *in vivo* experiment (Fig. 1), nothing near this amount of antibody could have been present in the washed cells (if the cells do not discriminate between fluorescein-labelled and unlabelled γ-globulins, their content of anti-LS globulins would be of the order of 80 μg/mg fibroblast protein according to the results given here). If, therefore, immunological inhibition were responsible for the decreased activities of lysosomal hydrolases in the homogenate of cells exposed to anti-LS globulins, interaction between the antibodies and the enzymes must have taken place in the living cells before homogenization, that is, within their lysosomes. Pinocytosis of the antibodies would indeed allow such a phenomenon to occur.

If the antibodies inhibit the lysosomal hydrolases within the lysosomes, digestion of pinocytized materials should be impaired. As a test of this possibility, fibroblasts were maintained for 4 days in the presence of 0·1 mg/ml. of fluorescein-labelled normal γ-globulins, as in the experiment of Fig. 4, but with 0·3 mg/ml. of anti-LS γ-globulins in the medium instead of normal γ-globulins. As shown in Fig. 5, degradation of the labelled protein was almost completely inhibited in the cells exposed to anti-LS globulins. It is, however, remarkable that the amount of undegraded fluorescein-labelled globulins stored in the cells hardly exceeded that found in non-inhibited cells (15·4 against 12·1 μg per mg fibroblast protein). This finding, for which we have at present no explanation, indicates either that pinocytosis was severely inhibited or that it was followed by considerable regurgitation, in the antibody-treated cells. It also suggests an alternative explanation for the lack of protein degradation, which could be a consequence of inhibited uptake rather than of impaired digestion. The almost complete absence of degradation products in the treated cells themselves, however, indicates that intralysosomal inhibition of the proteases by pinocytized antibodies played a significant part in the chain of events.

Another striking effect of the antibodies was observed on the glucose consumption of the cells, which amounted to 3·2 mg of glucose per day per mg fibroblast protein in the treated cells, against 1·3 mg per day per mg protein in the control cells. This effect was accompanied by a more rapid acidification of the medium, suggesting that part at least of the glucose consumed in excess was glycolysed to lactic acid.

Morphological Effects

Fibroblasts cultured for 4 days in medium containing either control rabbit γ-globulins or anti-LS globulins, as in the experiments of Figs. 4 and 5, were collected after trypsinization, washed with cold saline and fixed with 1 per cent osmium tetroxide in 0·1 M phosphate buffer (*p*H 7·4), in the presence of a minute amount of plasma proteins. The fixed cells were centrifuged and the pellet dehydrated and embedded in 'Epon'. Ultrathin sections were obtained with a Reichert OmU2 ultramicrotome. They were stained both with uranyl acetate and with lead citrate, and examined with a Siemens 'Elmiskop 1' at 80 kV. Typical micrographs are depicted in Fig. 6.

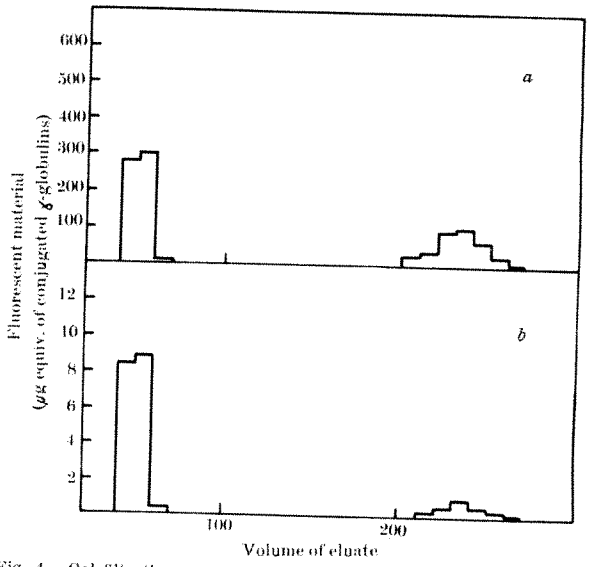

Fig. 4. Gel filtration on 'Sephadex G-50' of culture medium (*a*) and soluble cell extract of fibroblasts (*b*). The cells were cultured for 4 days in the presence of fluorescein-labelled control γ-globulins (0·1 mg/ml.) plus unlabelled control γ-globulins (0·3 mg/ml.). The initial peak corresponds to intact labelled γ-globulins, whereas the retarded peak is composed of low molecular weight products.

In the cells exposed to anti-LS antibodies, the cisternae of the endoplasmic reticulum are much less dilated than they are in the control fibroblasts. On the other hand, the treated cells show a striking increase in the size and number of cytoplasmic bodies of lysosomal type. In the control cells, these bodies are small and scattered irregularly in the cytoplasm. By contrast, the antibody-treated cells are literally packed with large granules of similar appearance. In both cells, the granules are bounded by a single membrane and have a pleiomorphic content.

The condition of "congestive enlargement of the lysosomes"[15] induced by the antibodies recalls that observed

in many congenital storage diseases, except that in the latter the lysosomal contents are made up of only a few specific chemical species which often have a characteristic appearance in the electron microscope[16]. Many storage diseases are now known to arise from a severe deficiency of a lysosomal hydrolase, essential for the further digestion of the substances that accumulate in the lysosomes. It is tempting to assume that we have artificially created here some sort of generalized storage syndrome by widespread inhibition of the lysosomal hydrolases by pinocytized antibodies. Because no accumulation of exogenous substances was revealed by the use of fluorescein-labelled globulins as indicator, it is most likely that the lysosomes are filled largely with endogenous constitutents segregated by autophagy. It remains to be seen, however, to what extent an enhancement of cellular autophagy, which is known to be stimulated by many metabolic stresses[15], may have contributed to the development of the syndrome.

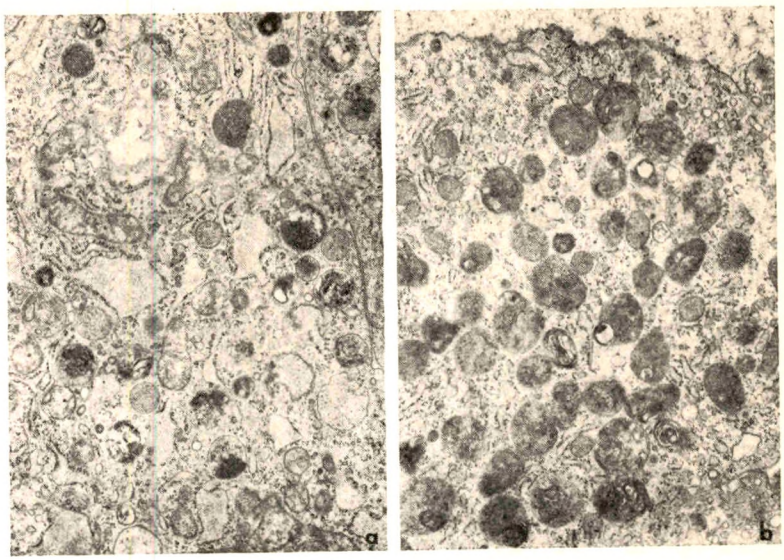

Fig. 6. Electron micrograph of cultured fibroblasts taken at the same magnification (×10,265). Cells maintained for 4 days in the presence of 0·3 mg/ml. of control γ-globulins (*a*) or of anti-LS γ-globulins (*b*).

Immunological Inhibition

Our results indicate that severe impairment of both the heterophagic and the autophagic functions of lysosomes[15] can be induced by exposure of cells to immunoglobulins inhibitory to their lysosomal hydrolases. In all likelihood, the antibodies exert this inhibitory effect within the lysosomes of the living cells, which they reach by the well established channel of pinocytosis followed by fusion of the pinocytic vacuoles with lysosomes.

It is, however, doubtful that this mechanism can account for all of our findings, in particular for the inhibited uptake of the conjugated protein. Other unresolved questions are the mechanism whereby the anti-LS globulins stimulate glycolysis and their possible influence on the rate of cellular autophagy. Also puzzling is the fact that cathepsin D was inhibited only by about 50 per cent in the homogenate of antibody-treated cells, whereas the breakdown of an exogenous protein by the same cells when intact was almost fully blocked. The conditions of the *in vitro* assay, however, are so far removed from those prevailing within lysosomes that too much significance should not be attached to this discrepancy. It is also possible that the primary attack of the conjugated γ-globulins involves an enzyme other and more strongly inhibited than cathepsin D, or that part of the protease is located within primary lysosomes that are neither accessible to pinocytized materials nor involved in intracellular digestion.

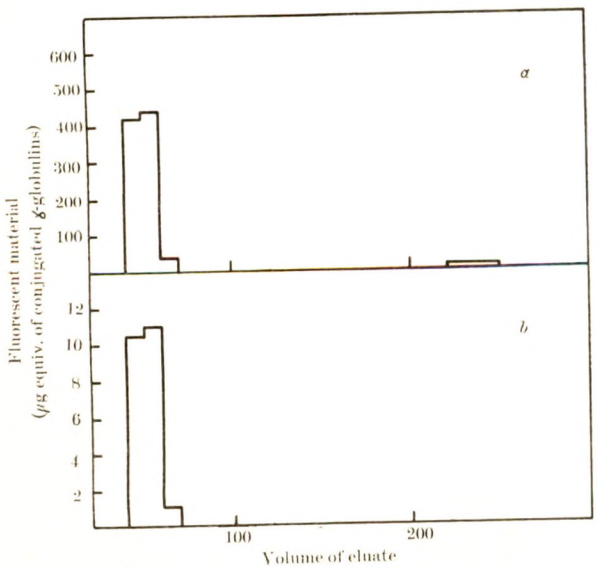

Fig. 5. Gel filtration on 'Sephadex G-50' of culture medium (*a*) and soluble cell extract of fibroblasts (*b*). The experiment was performed like that of Fig. 4 except that unlabelled anti-LS γ-globulins (0·3 mg/ml.) were substituted for the unlabelled control γ-globulins.

In spite of these complications, there seems little reason to doubt that a true immunological inhibition of lysosomal digestion has been achieved in these experiments. We therefore have a very valuable tool with which to explore a number of situations in which a role of lysosomes is suspected, but has not been demonstrated or assessed quantitatively. Our results also illustrate a new type of immunological cytotoxicity, not involving complement and dependent on an interaction with intracellular antigens.

We thank Drs Christian de Duve and Henri Beaufay for their help in the discussion of the results and in the preparation of this manuscript. This work has been supported by the Fonds de la Recherche Fondamentale Collective and by the US Public Health Service, National Institutes of Health. F. V. H. is supported by the Fonds de la Recherche Scientifique Médicale.

Incidence in River Water of *Escherichia coli* containing R Factors

by
H. WILLIAMS SMITH
The Animal Health Trust,
Stock,
Essex

Large numbers of *Escherichia coli* with antibiotic resistance transmissible to pathogenic organisms have been found in some British rivers. The principal source was insufficiently treated human sewage.

LARGELY as a consequence of the widespread use of antibiotics, R factors, which transfer antibiotic resistance among enterobacteria, have become common in the non-pathogenic *Escherichia coli* of the alimentary tract of man and domestic animals in the British Isles. Many R^+ organisms, especially those of human origin, would be expected ultimately to enter sewage and from this, possibly, rivers. I have therefore determined the incidence of such organisms in British rivers, paying here particular attention to *E. coli* with transmissible resistance to chloramphenicol, which is considered to be potentially the more dangerous because its resistance might be transmitted to *Salmonella typhi* and so render the treatment of typhoid fever more difficult. I also investigated the effect of sewage treatment on the survival of R^+ *E. coli*.

Coliform Counts

Samples of river water and sewage (100 ml.) were collected in sterile glass containers, and viable coliform organisms were counted by the method of Miles and Misra[1], using ordinary MacConkey's agar. Counts were also made on MacConkey's agar containing 15–20 μg/ml. of streptomycin, oxytetracycline, ampicillin, chloramphenicol, neomycin or sodium nalidixate to estimate the numbers of coliform organisms that were resistant to each antibiotic. Organisms were classed as coliform if they were Gram-negative and formed red colonies on MacConkey's agar similar in size to those of *E. coli*. When the number of these organisms in any particular specimen was expected to be low, one Petri plate of medium of each kind was also inoculated with 1·0 ml. of that specimen. A more intensive search was made for organisms resistant to chloramphenicol; where necessary, 20 ml. of each specimen was centrifuged and all the deposit was inoculated on to a plate of MacConkey's agar containing that antibiotic.

Faecal *E. coli* were identified by their ability to produce acid and gas in MacConkey's broth at 44° C (Eijkman's test), and then submitted to an antibiotic-sensitivity test; resistant organisms were further examined for transferable resistance.

To test for sensitivity and transferable resistance I used the methods of Smith[2]. Nalidixic acid-resistant mutants of a *lac*⁻ *Escherichia coli* K12F⁻, of *Salmonella typhimurium* of phage type 29, and *Salmonella typhi*, type A, were used as prospective recipient strains in the transfer tests. To test for transferability of nalidixic acid resistance, ampicillin-resistant mutants were used as prospective recipient strains instead of nalidixic acid-resistant strains.

Bacteriological Examination

Specimens of water for bacteriological examination were collected at ninety-eight sites on fifty-four British rivers or their tributaries. The results of some of these examinations are summarized in Table 1. The rivers Taff (Table 2), Trent, Severn and Thames were sampled at ten or more places. There was a great variation in the concentration of antibiotic-resistant coliform organisms in specimens examined from different sites, but there was a good degree of consistency in specimens collected from the same site at different times. Specimens containing low concentrations of antibiotic-resistant coliform bacteria had been taken from rivers that flowed almost entirely through rural areas, such as the Great Ouse and the Jed, or from places near the end of a long stretch flowing through a rural area, such as the Severn before Stourport and the Avon before Bristol. Specimens with high concentrations of resistant bacteria had usually been obtained from rivers after they had flowed through urban areas, such as the Ribble at Preston, the Avon after Bristol and the Tame

Table 1. CONCENTRATION OF ANTIBIOTIC-RESISTANT COLIFORM ORGANISMS IN SPECIMENS OF RIVER WATER

Origin of specimen	Viable coliform organisms/ml. resistant to C	T	S	Neo	Nal	A	Total

For other details see Table 1.

and Cole after Birmingham. Specimens from the Stour at Stourport and the Severn before and after entering this town demonstrated how a comparatively small heavily contaminated tributary can increase significantly the concentration of antibiotic-resistant coliform organisms of the river into which it flows. The appearance of the Stour and many of the other rivers containing large concentrations of antibiotic-resistant coliform organisms resembled that of raw sewage. All specimens taken in normal conditions from the river Thames, into which large quantities of treated sewage, particularly at London, are discharged, yielded comparatively few antibiotic-resistant coliform organisms. The concentration was considerably higher in water collected at Westminster during a partial strike of sewage workers than in water collected at the same place when sewage works along the Thames were functioning normally.

No coliform organisms were found in the specimen taken from the Taff immediately before Merthyr Tydvil or in that taken from its main tributary the Rhondda Fawr, immediately before Tynewydd (Table 2). Above these two points, both rivers flow through hilly regions inhabited almost solely by a few sheep. For the rest of their courses, they flow through densely populated urban areas containing very few farm animals. There are no licensed abattoirs between Merthyr Tydvil and Whitchurch, the stretch of the Taff from which specimens yielding high concentrations of antibiotic-resistant coliform organisms were taken. Between Aberfan and Cilfynydd sewage was known to be discharged into the Taff and from the appearance of this section of the river it was obviously insufficiently treated. Sewage from Pontypridd and from the other human habitations between this town and Cardiff is discharged directly into the sea. The specimens collected from the Taff after it has passed through Pontypridd revealed a decreasing incidence of antibiotic-resistant coliform organisms.

Very few coliform organisms were found in specimens collected at rural locations of canals in the Midlands.

Faecal *E. coli* in River Water

The Eikjman test was performed on a representative collection of coliform organisms isolated from river water (Table 3). No more than five cultures of the "total" coliform organisms and of those which were resistant to ampicillin and chloramphenicol were examined from any one specimen of river water. All cultures of coliform organisms resistant to the other antibiotics had been isolated from different specimens. On the basis of these tests, most of the coliform organisms resistant to chloramphenicol, tetracycline, streptomycin or neomycin were classified as faecal *E. coli*; only a minority of the ampicillin-resistant coliform organisms and the "total" coliform organisms were so classified.

Of 435 chloramphenicol-resistant strains of *E. coli* isolated from ninety specimens of river water, 373 were found to transfer their resistance to *E. coli* K12F⁻ and 208 to *Salmonella typhimurium* of phage type 29. Of forty strains that transferred their chloramphenicol resistance to *E. coli* K12F⁻, thirty-six also transferred it to *Salmonella typhi*; all forty had been isolated from different specimens of river water. None of the 278 chloramphenicol-resistant strains was resistant to chloramphenicol only; 179 were resistant to five or more antibiotics, the commonest pattern involving resistance to chloramphenicol, ampicillin, streptomycin, tetracyclines and sulphonamides.

Twelve of twenty tetracycline-resistant strains of *E. coli* from different specimens transmitted their resistance to *E. coli* K12F⁻. The corresponding figures for four groups of twenty strains, each group resistant to neomycin, ampicillin, streptomycin or nalidixic acid, were twenty, thirteen, twelve and nil respectively.

Table 3. INCIDENCE OF FAECAL *Escherichia coli* AMONG COLIFORM ORGANISMS ISOLATED FROM RIVER WATER

Strains classed as	No. examined	No. that were faecal *E. coli**
Chloramphenicol-resistant	293	269
Tetracycline-resistant	21	20
Streptomycin-resistant	32	20
Neomycin-resistant	20	20
Nalidixic acid-resistant	40	19
Ampicillin-resistant	182	38
"Total"	340	94

* *E. coli* which reacted positively in the Eijkman test.

Effect of Treatment on Sewage

Numbers of viable antibiotic-resistant coliform organisms in sewage entering and leaving six sewage treatment works in the Basildon area of Essex are summarized in Table 4. At the largest works, which serves an area of some 70,000 inhabitants, the activated sludge method is used. The other five together serve a slightly smaller population and the biological filter method is used; the results for these five are grouped together in the table because they resembled each other closely. In all the examinations carried out at all six works, the concentration of antibiotic-resistant coliform organisms was always much lower in the effluent than in the influent sewage. The distribution of faecal *E. coli* among chloramphenicol-resistant coliform organisms was similar to that found in river water.

Importance of Sewage Treatment

The results of my investigation, expressed as viable organisms per millilitre, shows that some British rivers contain many antibiotic-resistant *E. coli*. Because much of their resistance, particularly to chloramphenicol, was transmissible to *Salmonella typhi* and *typhimurium*, this is an undesirable situation.

Available evidence incriminates human beings, through sewage, rather than animals as the main source of the resistant *E. coli*. For example, the incidence of antibiotic-resistant organisms in general was low in rivers and canals that flowed principally through rural areas and high in rivers that flowed through urban areas; in rivers with the highest incidence it was obvious, to eye and nose, that inadequately treated sewage was being discharged into them. The river Taff provided the strongest evidence incriminating human beings. No antibiotic-resistant *E. coli* were found in this river before it entered the predominantly urban area, whereas many were found in the stretch of the river that received inadequately treated sewage from the upper part of this area, where there were no abattoirs. Progressively

Table 4. EFFECT OF TREATMENT ON THE NUMBERS OF ANTIBIOTIC-RESISTANT COLIFORM ORGANISMS IN SEWAGE

Method of treatment	Material examined	Viable coliform organisms per ml.* resistant to C	T	S	Neo	Nal	A	Total
Biological filter	Influent	1,500 (50–5,000)	7,500 (1,000–50,000)	7,500 (2,500–25,000)	200 (50–1,500)	10 (0–100)	50,000 (2,500–150,000)	125,000 (25,000–500,000)
	Effluent	15 (0–500)	120 (20–1,500)	125 (20–5,000)	1 (0–10)	0 (0–40)	1,200 (80–5,000)	2,500 (750–50,000)
Activated sludge	Influent	2,000 (250–4,000)	10,000 (2,500–120,000)	20,000 (4,000–25,000)	250 (100–2,500)	50 (30–1,000)	50,000 (20,000–150,000)	200,000 (100,000–1,000,000)
	Effluent	20 (10–40)	60 (40–150)	60 (40–200)	8 (3–50)	1 (0–4)	500 (100–7,500)	5,000 (1,500–15,000)

* Median count followed by, in parentheses, the range of the counts for twenty-four influent and twenty-four effluent samples obtained from five "biological filter" sewage works and for seven influent and seven effluent samples obtained from an "activated sludge" sewage works; no more than one influent and one effluent sample were obtained on any one day.
For other details see Table 1.

fewer resistant coliforms were found in specimens collected in the lower part of the urban area, where sewage was not discharged into the river.

Sturtevant and Feary[3] in the United States observed no reduction in the concentration of antibiotic-resistant *E. coli* in sewage as a result of treatment at sewage works. My results were quite different. The difference between the two sets of results could be a consequence of the use of different methods of treatment. Certainly, the biological filter and the activated sludge methods, as applied in the six sewage works in the Basildon area, produced a marked reduction in the concentration of antibiotic-resistant *E. coli*, so much so that it is probable that their universal application in Britain would significantly reduce the antibiotic-resistant *E. coli* entering the rivers.

The presence of antibiotic-resistant *E. coli* in river water is not solely a British problem. R^+ organisms, including those resistant to chloramphenicol, were found in fairly large numbers in water collected from the Hudson river in New York. Incidentally, one strain of *E. coli* obtained from this water was one of the highest transmitters of chloramphenicol-resistance found in this present investigation.

I thank Miss Carole Smith and Miss Diane Poulton for technical assistance and Mr Wadsworth of the Basildon Urban District Council and Mr Harris of the Basildon Development Corporation for providing facilities at their sewage works. This work was supported by a grant from the Medical Research Council.

Differential Reactions of Atlantic and Pacific Predators to Sea Snakes

by

I. RUBINOFF
C. KROPACH

Smithsonian Tropical Research Institute,
Box 2072,
Balboa, Canal Zone

Predators from the Pacific made no attempt to attack the Pacific sea snake *Pelamis platurus*. Atlantic predators, however, were more inclined to attack, sometimes being wounded by their prey. This suggests that if a canal in Central America facilitated the spread of *Pelamis* to the Atlantic, the species would eventually spread throughout the ocean as selection favoured predators disinclined to attack it.

If a sea level canal is built in Central America[1,2] abundant populations of *Pelamis platurus* could reach the Atlantic Ocean from the eastern Pacific. Very little is known about the behaviour and ecology of this venomous reptile, which is widespread in tropical and subtropical waters from the east coast of Africa to the west coast of Central and South America. Known as the yellow bellied sea-snake, it reached the eastern Pacific relatively recently, presumably in the 2 or 3 million years since the rise of the Isthmus of Panama.

We have attempted to evaluate the relationships of *Pelamis* to Pacific predators and to potential Atlantic predators. We have examined the reactions of eastern Pacific predators to *Pelamis* both in the field and in the laboratory, and studied the response of naive Atlantic predators to *P. platurus*.

Search for Natural Predators

Pelamis is ovoviviporous and spends its entire life at sea. Although individuals can dive for up to 1 h they spend much time at or near the surface. In the sea it will spend more than 30 min, more or less motionless, at the surface. *Pelamis* swims relatively slowly and its yellow and black colour and behaviour make it visible and recognizable from farther away than a similarly sized stick or dull coloured animal would be. Specimens are usually easy to capture—we usually catch them from the surface of drift lines with a dip-net. The sluggish habits of the species would be likely to make *Pelamis* potentially vulnerable to a wide range of fish and avian predators.

Wetmore reports seeing *Fregata magnificens* pick up *Pelamis*, fly off, and then drop them without further interest[3]. We have occasionally captured specimens with healed wounds, shaped as though caused by bird beaks. *Pelamis* have not, however, been found in the stomach contents of any sea bird and in many hours of observations we have never witnessed an attack. Neither have we found any evidence of *Pelamis* in the stomach contents of 420 specimens, including twenty-six species of bony and cartilaginous fishes, taken in Panama Bay (between 7° 30′ and 8° 55′ N latitude and 78° 10′ and 80° 0′ W longitude) usually near drift lines containing *Pelamis*.

Reaction of Captive Pacific Predators

Several carnivorous Pacific fishes (*Ginglymostoma*, *Epinephelus*, *Lutjanus*, *Centropomus* and *Scianus*) were established in 15–70,000 gallon tanks of sea water. They were all willing to attack and feed on living anchovies and carangids and after 10 days of acclimatization they were given only specimens of *Pelamis* for 20 min each day. The predators swam to within approximately 12 inches of the snake, stopped to make an inspection and then usually showed no further interest. During more than 30 days no predatory behaviour developed towards *Pelamis*. In some cases when snakes were left in a tank with a predator the latter starved rather than attempt to feed on them. On one occasion a snapper which had become conditioned to seize live food thrown from the surface ingested a snake as it hit the water, before it could have seen or smelt the fish below the surface. It immediately spat out the snake and paid no further attention to it.

Reaction of Captive Atlantic Predators

To test the reactions of naive Atlantic predators to intact *Pelamis*, relatively large specimens of *Lutjanus* spp. were established in concrete tanks and treated in a similar manner to the Pacific predators before being presented with *Pelamis*.

Pelamis represented a new shape, pattern and smell to these fishes. On the initial encounters the Atlantic predators showed interest, swam close for examination

Table 1. SUMMARY OF TESTS OFFERING LIVE *Pelamis* TO CAPTIVE PREDATORS

	No. of species	No. of specimens	No. of trials	No. of attacks	No. of predator deaths
Pacific	10	21	316	1	0
Atlantic	9	21	383	35	3

and followed the snakes for varying periods. Usually, by the tenth trial the more aggressive of the snappers attacked the *Pelamis*. Attacks were usually directed toward the head and ingestion was rapid, being completed in less than 10 s. Two snakes were taken tail first; one of them bit the fish under the eye just before it was completely swallowed. The fish died in 20 min. On several occasions the Atlantic fishes ingested several snakes consecutively. The survival of Atlantic fishes ingesting *Pelamis* varied. Some fish ate an occasional *Pelamis* with impunity, one was killed when eating its first snake and another relatively efficient predator consumed twenty-two snakes in 31 days before succumbing to a snake bite. Table 1 summarizes the results of the feeding experiments with Atlantic and Pacific predators.

Evolution of *Pelamis* Recognition

The Pacific predators which do not eat sea snakes seem to have been selected for a strong aversion to *Pelamis*. Atlantic predators, on the other hand, will feed on live *Pelamis*, and after the first meal more are accepted without hesitation. One 18 inch snapper ingested four 12 inch *Pelamis* in less than 20 min. On one occasion an Atlantic snapper ingested two sea snakes consecutively. The fish died within 1 h, presumably the victim of an internal bite, for no biting was observed during attacking and swallowing. Both sea snakes were regurgitated after about 1 h and both subsequently survived. This may help to explain the evolution of the highly toxic venom which *Pelamis* possesses. Since the fish victim almost always dies, how then has selection produced a venom more toxic than the terrestrial snakes from which sea snakes have evolved? The food of *Pelamis* is not usually envenomated, so that selection for trophic efficiency is probably not a primary factor. The common explanation that a predator might learn to avoid snakes after surviving a sub-lethal bite does not seem to apply in this case. But if a dying fish which has eaten a sea snake and been bitten occasionally regurgitates a snake, selective mechanism for increasing the potency of the venom may be at work.

What will happen when Pacific predators witness successful predation on *Pelamis* by Atlantic fishes (if the canal is built through the geographical barrier)? One of the most powerful stimuli to feeding in fish is for them to witness feeding by other fishes. When we offered sea snakes to Atlantic and Pacific fishes together, the attack and ingestion of *Pelamis* by Atlantic fishes produced excitement and close inspection by the Pacific predators, but no attempt to eat a snake was observed. Sometimes two or more Atlantic snappers fought for a single snake. A Pacific snapper might be attracted to and follow an Atlantic snapper with a partially ingested snake, but we saw no attempts to take it away.

It is possible that the brilliant and conspicuous colour pattern of *Pelamis* is aposematic and that potential predators have been selected to avoid it. In the most common pattern about 75–85 per cent of the body is uniformly black dorsally, yellow midlaterally and brownish ventrally. The lateral and ventral colour is more similar after shedding and the ventral darkening becomes more pronounced with "ageing" of the skin. The tail is covered with black spots on a yellow background; the size and distribution of the spots are individually specific as a finger print. We have examined the distribution of body pattern uniformity in 167 specimens of *Pelamis*. All degrees of intermediate conditions appear between the "standard type" (15–25 per cent of the body spotted as in the left-hand specimen of Fig. 1) and spotting completely up to and including the head (as in the right-hand specimen of Fig. 1). Yellow specimens with reduced spotting have also been observed (personal communication from Dunson and Voris). The variation in pattern has been observed in all age classes, with about equal frequency, so that deviation from the "standard" does not seem to be particularly deleterious.

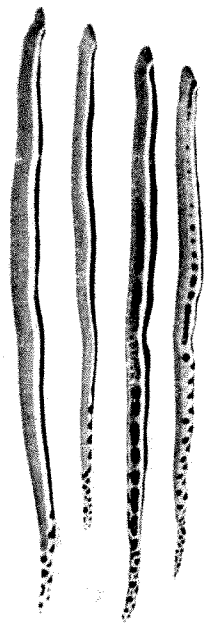

Fig. 1. Examples of pattern variability in *Pelamis platurus* from Panama Bay.

With few exceptions polymorphism (even conspicuous continuous variation) is uncommon in aposematic organisms[4]. The usual explanation for this is that in most circumstances it is not advantageous for aposematic organisms to have variations in pattern which may confuse predators, which if they have been selected for or have learned to avoid a particular colour or pattern may be unable to associate variations with the "standard" and may attack when they should not. If a sensory clue other than vision were important in the predator's recognition of *Pelamis* it might be possible to explain the variation in colour pattern as a relaxation of selection for the "standard" phenotype. In our aquaria two adult Pacific nurse sharks *Ginglymostoma cirratum*, which are essentially scavengers and/or olfactory predators, refused to eat living or dead *Pelamis*. In February 1970, two juvenile *G. cirratum* were captured. One was probably not more than a few weeks old, and it is unlikely that either of them had experienced contact with *Pelamis* in the inshore areas from which they were taken. No *Pelamis* had been reported there for several months. The sharks were quickly trained to accept food from forceps, and offered pieces of fresh and frozen sea snake. All were rejected. They could discriminate between similarly sized and shaped pieces of squid and pieces of sea snake. If *Pelamis* were sandwiched inside the mantle of a squid the sharks would ingest it, mouth the morsel for a few seconds then swallow the squid and expel the snake. These observations suggest that not only visual clues are used by predators to recognize *Pelamis*.

Using felt marking pens we changed the colour of specimens of *Pelamis* to all black or black and red. All of these were rejected by Pacific predators and so were freshly killed and skinned snakes. Feeding frenzies can be produced in captive predators by throwing living anchovies into the tank, but even in these circumstances

of very aggressive, competitive feeding, the fishes discriminated 100 per cent against *Pelamis*. All Pacific predators examined refused to eat living or dead (whole or cut up) *Pelamis* with skins on or off.

Our observations suggest that Pacific fishes can recognize *Pelamis* by visual, olfactory, and/or gustatory clues. The relative importance of the different modalities may, of course, vary from species to species. Aposematic visual aspects seem to be only part of the recognition criteria, although formerly they may have been more important. If conspicuously (but not similarly) coloured ophichtid eels were offered to Pacific fishes they were immediately attacked and eaten. The general serpentine shape and bright colours are thus not necessarily avoided by these predators.

Future Prospects

Pelamis platurus does not have characteristics which are universally avoided by marine fishes. Avoidance of *Pelamis* seems to be specifically selected for in organisms which have direct contact with them. In Central America the avoidance reaction has probably evolved to its present level in less than 3 million years, or rather less than the time since the rise of the Isthmus, after which *Pelamis*, presumably, arrived in the New World.

It is possible to speculate on the colonization potential of *Pelamis* if they are afforded access to the Atlantic. Large numbers of *Pelamis* are periodically stranded or appear swimming along the Pacific shores of Panama and they represent potential propagules through an unobstructed sea level canal. There seems to be no habitat requirement of *Pelamis* which could not be satisfied in the Atlantic. Drift lines of debris attracting the small fishes which constitute much of the food of *Pelamis* are found in both oceans. Drifts of Sargasso weed would probably provide ideal feeding grounds for *Pelamis*.

Invading *Pelamis* would probably be heavily preyed on so that their initial movement would be inhibited. But selection would quickly favour predators that are unwilling to attack *Pelamis* (even if only one out of twenty-two meals results in the death of the predator, this is a very high selection rate). The development of avoidance reaction in predatory species would follow. If a sea level canal were built the probability of these animals eventually colonizing the tropical Atlantic would be great, but predation by Atlantic carnivores would probably reduce the speed of this colonization.

Evidence that Polywater is a Colloidal Silicate Sol

by
WILLARD D. BASCOM
EDWARD J. BROOKS
BRADFORD N. WORTHINGTON, III
Naval Research Laboratory,
Washington, DC 20390

Analysis of residues from condensation of "polywater" using the electron probe showed significant amounts of silicon and sodium, suggesting that the unusual properties of "polywater" may be due to the presence of silica or silicate.

Deryaguin and co-workers have presented evidence that a new form of water (anomalous water) is produced when normal water vapour condenses into minute, pristine glass or silica capillaries[1,2]. More recently, Lippincott *et al.*[3] produced water condensate in such capillaries and obtained its infrared and Raman spectra, from which they concluded that the condensate contained a high molecular weight polymeric form of water, or "polywater". A distinction should be made between the claims of Lippincott *et al.* for "polywater" and those of Deryaguin *et al.* for anomalous water. The Russian workers do not claim that anomalous water is a high molecular weight polymeric water. Furthermore, they were extraordinarily careful in preventing electrolyte contamination of the condensate in many of their experiments. The work reported here indicates that salt contamination is an important consideration in the experiments described by Lippincott *et al.*

The Experiments

Capillaries with internal diameters of 50 μm to 5 μm were drawn from acid (HNO_3–H_2SO_4, 1 : 1) cleaned 'Pyrex' and silica (GE 204) tubing. In some experiments the capillaries were loosely placed in 'Pyrex' dishes over distilled water in a desiccator evacuated to about 40 mm Hg and held at 25° ± 1° C. This is the procedure used by Lippincott *et al.*[3]. Other condensation experiments were conducted in an apparatus designed to allow the capillaries to be evacuated independently of the water to reduce the chance of spray reaching the capillaries during the pump-down. The apparatus had a chamber for the capillaries separated from the chamber for water by a grease-free vacuum valve. The water chamber was evacuated first, the valve closed and the capillaries introduced into the other chamber. This section was then evacuated, cut off from the pump and opened to the water.

The capillaries were inspected after 3–10 days' exposure to water vapour. To remove condensate for analysis, the liquid was expelled by air pressure using a gas tight syringe and hypodermic needle. The capillary was sealed into the needle with a drop of melted, purified paraffin. The condensate was expelled on to steel mirror surfaces and the residue examined by light microscopy. For electron probe analysis a pure, low-silicon copper was used instead of steel. The electron probe was an Applied Research Laboratory EMX 200. Infrared spectroscopic determinations were made with a Perkin–Elmer 457 spectrometer.

Silicon and Sodium in Condensate

Condensate was observed in both 'Pyrex' and silica capillaries held over distilled water. For the capillaries in the desiccators the yield (number of capillaries with condensate) was about 50 per cent. In the two-chamber apparatus the yield was 10–25 per cent. Fig. 1*A* illustrates the appearance of condensate columns viewed with

a reflected light microscope. When these capillaries were put in an evacuated chamber or left at 40–50 per cent relative humidity for a few hours, most of the condensate evaporated except for a residue with a gel-like appearance. In Fig. 1*B* the gel had formed before the liquid phase had fully evaporated.

Much of the condensate evaporated very rapidly when expelled on to steel mirror surfaces, leaving behind minute films of residue, some of which have a particulate appearance (Fig. 2). Close examination revealed that many had ridges near the edge, indicating a profile such as in Fig. 3.

Residues from condensate in silica usually had a more homogeneous appearance (Fig. 4) than those from 'Pyrex'. The only particles that could be clearly associated with the silica derived residues are those clustered at the centre in Fig. 4. Other particles in the photograph are dust.

Electron probe analysis of the residues from 'Pyrex' revealed sodium and silicon in easily detectable amounts. Sodium was most strongly evident in the particulate matter within the residue and the silicon level was highest near the edge. These analyses were not pursued in detail because the corrosion of pristine glass surfaces is well known and the presence of sodium and silicon was not unexpected.

The residues from condensate in silica were thinner and therefore more difficult to analyse than the residues from 'Pyrex'. Nonetheless, the electron probe revealed significant levels of sodium and silicon in the thicker

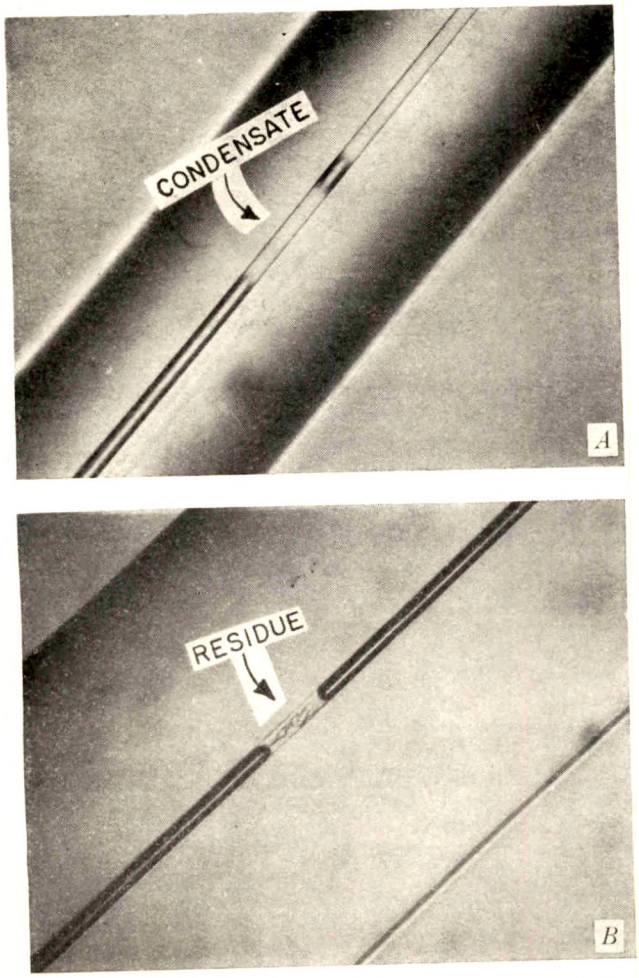

Fig. 1. Appearance of water condensate in a silica capillary immediately after removal from desiccator (*A*) and after most of condensate had evaporated (*B*). Capillary inner diameter is about 30 μm.

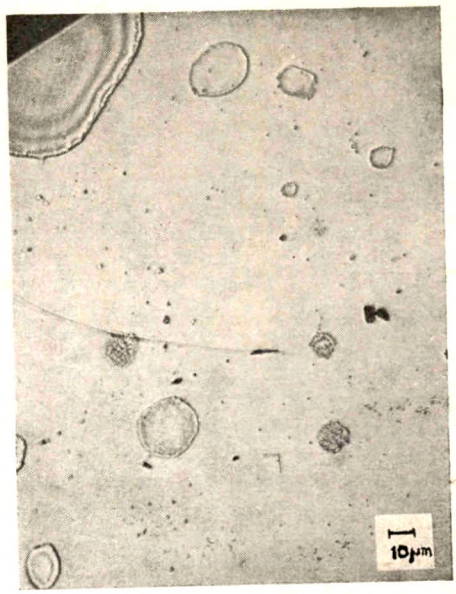

Fig. 2. Residues left by condensate formed in 'Pyrex' and expelled on to a steel mirror.

Fig. 3. Residue profile.

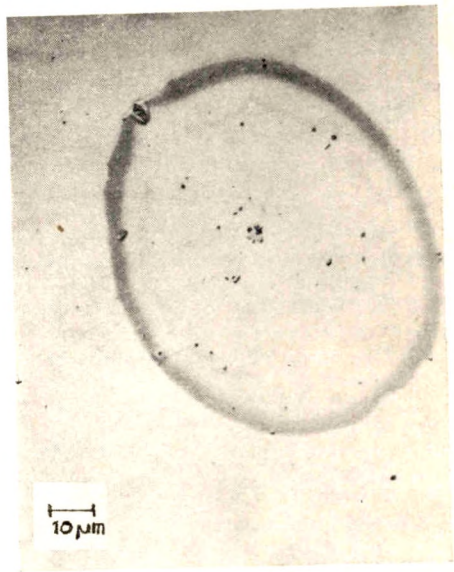

Fig. 4. Residue from condensate formed in silica and expelled on to a steel mirror.

regions near the edges. Fig. 5*A* shows the secondary electron emission for such a region and *B* shows the silicon X-ray (SiKα 7.1252) emission from this same region. The silicon level in this residue is about four times the background level. The relative intensities for silicon and sodium were approximately equal.

Residues of dilute sodium silicate solutions also showed the annular profile drawn in Fig. 3. Analysis of these residues with the electron probe revealed that it was often impossible to detect significant amounts of sodium or silicon in the thin central regions. For example, in Fig. 6 the silicon X-ray emission is displayed for a section of a sodium silicate residue left by a 0·1 μl. drop or a 0·1

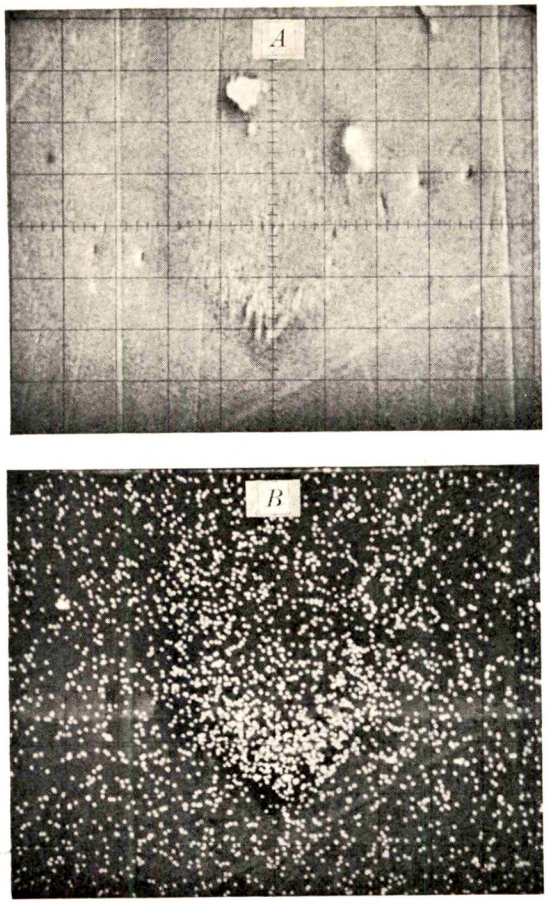

Fig. 5. Electron probe secondary electron emission (*A*) and silicon. X-ray emission (*B*) for a residue of condensate from silica. Cu substrate.

per cent solution. The arc of the rim clearly shows emission due to silicon but no significant emission is observed for the central region even though material was visible with the light microscope.

We conclude from the electron probe results that silicon, sodium and possibly other cations are important if not principal constituents of these condensate residues. Failure to detect these elements in earlier work[3] may have occurred because the residues were too thin.

Infrared Spectra of "Polywater"

If silicates are part of the condensate, then it is possible to offer an alternative explanation for the infrared spectra of "polywater". Silicate solutions are quite alkaline and are thus capable of absorbing CO_2 from the atmosphere. The principal bands in the "polywater" spectrum are at 1,600 cm^{-1} and 1,400 cm^{-1} which are close to the frequencies for the antisymmetric and symmetric O–C–O stretching vibrations. To test this idea infrared spectra were obtained for residues left by drops of bicarbonate–silicate solutions on Irtran 2 plates. A typical result is given in Fig. 7 for the residue from a solution containing 1·5 g/l. of sodium silicate (mole ratio $SiO_2 : Na_2O = 3{\cdot}3$) and 2·6 g/l. of $KHCO_3$. The bands at 1,650, 1,400 and 830 cm^{-1} are caused by bicarbonate and these same bands can be seen in the polywater spectra[3,4]. The broad band at 1,200–1,000 cm^{-1} is caused by silicate and the one between 3,700 cm^{-1} and 2,200 cm^{-1} is probably from residual water.

The spectrum given in Fig. 7 differs from the spectra reported for "polywater", just as the "polywater" spectra differ themselves[3,4]. After a study of the infrared spectra of a variety of bicarbonate–silicate mixtures, the reasons for these differences in the spectra became clear. It was found that the band intensities, positions and shapes were a function of (*a*) total solids concentration, (*b*) ratio of silicate to bicarbonate, (*c*) mole ratio of Na_2O and SiO_2, (*d*) age of the solution and the residue, (*e*) the rate and manner in which the solution dries, and (*f*) the presence of other anions or cations. It is believed that different combinations of these factors gave rise to the observed spectra. For example, the band at 1,650 cm^{-1} in Fig. 7 does not correspond exactly with the 1,600 cm^{-1} band for "polywater"[3,4]. When the bicarbonate–silicate residues were aged for a few days, however, there was a detectable shift of the band to 1,625 cm^{-1} and sometimes lower.

Origin of Silicate Anion

In these experiments the silicate anion could easily originate from a surface corrosion of the capillary walls. The surface hydrolysis of silicate glasses, especially pristine (freshly formed) surfaces, is well known[5]. The process involves the hydration of cationic sites to form an alkaline film capable of hydrolysing the silicate network. Frazer *et al.*[6] describe water adsorption on the inside of freshly blown glass bulbs and observed a visible condensate which they found to be strongly alkaline. They were also able to show that the alkaline film had left the surface rough and porous.

Fig. 6. Electron probe silicon X-ray emission for a sector of a residue left by a drop of sodium silicate solution. Cu substrate.

In the case of condensate from silica capillaries, the electron probe gave clear evidence of sodium as well as silicon which implies contamination because the silica itself does not contain significant amounts of sodium. The principal source of this contamination was probably the glassware holding the capillaries; the formation of a mist or spray from the water during pump-down is believed negligible, especially in the two chamber apparatus. Contamination from the glassware would occur if a water film sufficient to allow surface diffusion or creep of electrolyte on to and into the capillaries developed on the walls. In this connexion, it was noted that in all the condensation experiments there was clear evidence of moisture on the walls of the apparatus, formed, no doubt, during small fluctuations in the room temperature. Moreover, if the 'Pyrex' dish holding the capillaries was replaced with a polyethylene dish where the surface creep should be much reduced, the yield dropped from the usual 50 to about 15 per cent.

Undoubtedly the contaminating salts can contribute to the corrosion of the pristine silica surface but, even with silica, such contamination may not be essential. Silica surfaces offer Si—OH groups for water adsorption and at monolayer coverage and higher ($P/Po > 0{\cdot}4$) the film is mobile[7]. This film is also acidic, for conductivity studies

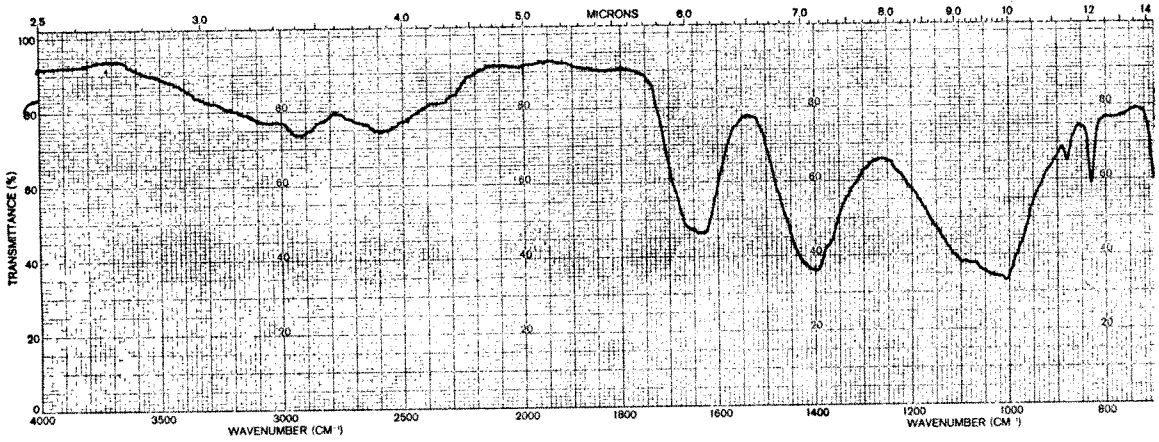

Fig. 7. Infrared spectrum of residue of a sodium bicarbonate–silicate mixture.

indicate the charge carrier is H^+ or H_2O^+[7]. An acid-catalysed surface corrosion may therefore occur, especially on a pristine surface in which many Si—O—Si bonds are strained.

Initially, the corrosion product of silica or 'Pyrex' would be silicic acid (or metal silicate) which would condense quickly into a colloidal silicate sol and ultimately to a colloidal gel if the solution is dried. Many of the properties attributed to "polywater", such as the gel-like appearance[3,8] and the birefringence[8,9] of the condensate residues, certainly suggest silicate. The high refractive indices reported for polywater[9] are also consistent with silicate solutions containing high proportions of metal cation[10].

The results reported here offer alternative explanations for the "polywater" phenomena. Samples of "anomalous water" prepared by the technique of Deryaguin and co-workers have not yet been studied. They obtained condensate in very pure silica capillaries held in a platinum fixture with distilled water as the source of vapour[1]. This experiment would seem to remove any possibility of contamination by electrolyte. An acid-catalysed corrosion of pristine silica by adsorbed water alone, however, may lead to a silica sol, which could explain many of the anomalous properties they observed. We now hope to repeat these experiments and analyse the condensate.

Plate Tectonics of the Scotia Sea Region

by
P. F. BARKER
Department of Geology,
University of Birmingham

A newly defined small lithospheric plate in the eastern Scotia Sea accounts for the intense seismicity at the South Sandwich Trench.

THE relative motion of the South American and Antarctic lithospheric plates is not exactly known, and at present the distribution of earthquake epicentres[1,2] cannot alone be used to determine the precise path of the boundary between them. A model for the plate boundaries and motions is presented below which is based additionally on recently published marine geophysical data from the Scotia Sea region[3–7]. These data also bear on the origin of the Scotia Ridge which has long been at issue[8–11].

I presume that the boundary between the South American and Antarctic plates runs between the point where the Chile Rise[12,13] meets the Peru–Chile Trench at 45° S, 76° W, and the Mid-Atlantic Ridge at 55° S, 1° W. Three earthquake epicentres on Fig. 1 (part of Plate 3 from ref. 2) lie along the west coast of Chile, south of 45° S; three others are associated with the north Scotia Ridge, rather more with the southern limb, and others lie in deep water areas west of the South Sandwich Islands and in the far west Scotia Sea (Drake Passage). Intermediate depth shocks, down to 170 km[2,14], supplement the anomalous, intense shallow activity associated with the volcanic South Sandwich Island arc, from the southern end of which a zigzag line of epicentres extends eastward to the Mid-Atlantic Ridge. The sparseness and diffuse distribution of earthquake epicentres over most of this region cannot be attributed entirely to the effect of a relatively unfavourable distribution of recording stations; indeed, if only the larger amplitude shocks are being detected then computed epicentres are less easily dismissed as being of secondary importance and plate boundaries are required to be of complex shape.

A total separation of 1·6 cm/year along 290° of the

South American and Antarctic plates close to the South Atlantic triple junction is obtained by combining the known relative motion between South America and Africa[15] with preliminary spreading rate data from the Atlantic–Indian Ridge[16]. This estimate is approximate and does not apply to the more westerly parts of the boundary as the pole of rotation is unknown. But it seems that relative motion is small over the whole of the boundary, which may account for the sparse and discontinuous earthquake epicentre distribution.

Magnetic Lineations

Trends and ages of correlated and dated magnetic anomalies within the Scotia Sea are shown in Fig. 2 (from ref. 4). Dating is with respect to the Magnetic Reversal Time Scale of Heirtzler *et al.*[17].

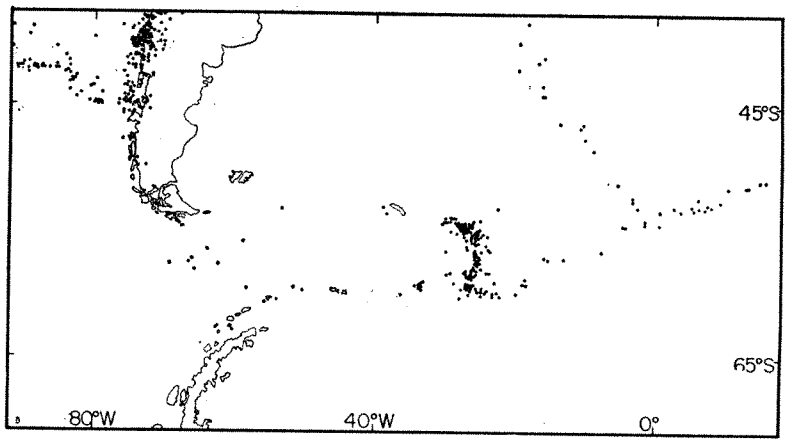

Fig. 1. Distribution of epicentres of shallow focus (< 100 km) earthquakes in the Scotia Sea region[2].

In southern Drake Passage, that part of the Time Scale between 8 and 15 m.y. is recognized in three sections, separated by orthogonal fracture zones which in most places have topographic expression. The easternmost lies on a line joining prominent bathymetric ridges extending north-westward from Elephant Island and south-eastward from near Cape Horn. For convenience the name "Shackleton Fracture Zone" is used for this feature, after the British Antarctic Survey ship aboard which the data were acquired. A spreading rate of 2·4 cm/yr along 130° fits all three sections and Lamont anomaly 6 (21 m.y.) occurs on one profile crossing the easternmost section in a position consistent with extrapolation south-eastward at the same spreading rate. Further extrapolation south-eastward at this rate gives ages of 15 m.y., 20 m.y., and 25 m.y. for the three sea-floor sections at the axis of the trench-like feature which lies in front of the South Shetland Islands between 57° W and 64° W. Unlike Smith Island to the south-west and the Elephant Island group to the north-east, the central South Shetland Islands opposite the trench have a history of late Tertiary andesitic volcanic activity[18]. The isostatic gravity anomaly over the trench[5] is similar to that over island arcs but of smaller amplitude. The lack of earthquake activity shows that the trench is now inactive, but all other features combine to suggest that Pacific crust was being consumed there during much of the late Tertiary.

If these exist, extrapolation along 310°, also at 2·4 cm/yr, would place the three 0 m.y. spreading centres approximately en echelon along a north–south line at 67° W, coinciding with an elevated zone of rough topography separating the Scotia Sea from the deeper, smoother Pacific–Antarctic Basin. I consider, however, that since the South Shetland trench is inactive, this centre is unlikely to be still spreading at 2·4 cm/yr/side, if at all.

East of the Shackleton Fracture Zone, anomaly shapes are apparently much less consistent along the strike, and navigational uncertainties greater. The trend of anomalies here lies parallel to those farther west, and to a double bathymetric ridge lying roughly centrally in eastern Drake Passage. The central valley of this ridge, shown by closed circles in Fig. 2, is followed by a single magnetic anomaly for much of its length, and on two profiles a limited symmetry about this anomaly can be seen. Anomaly offsets coincide with two of the ridge's transverse dissecting troughs. I can identify in the magnetic profiles, equally inconclusively, several conflicting sequences from the Reversal Time Scale, including one which accepts the possible correlation of Lamont anomaly 6 across the Shackleton Fracture Zone. Some of the correlations are of poor quality, but probably the general anomaly trend is correct and the central double bathymetric ridge will prove to be or to have been a spreading centre. Provisionally, a late Tertiary to Recent age for this spreading is assumed, by comparison with the dated sea floor to the west. A lower spreading rate than that measured to the west is consistent with the absence of a trench at either margin and perhaps explains the less consistent anomaly shapes.

Farther east, between South Georgia and the South Orkney Islands, the shape consistency of the anomalies and the navigation are again relatively poor. Trends are different and oceanic anomalies occur mainly to the north of an abrupt boundary at 58° S. Large smooth-surfaced blocks occurring to the south of 58° S show a depth and crustal structure intermediate between that of continent and ocean, and are separated by small areas of apparently normal oceanic crust[4]. Magnetic anomalies here, occurring amid large areas of undisturbed magnetic field, are as likely to be caused by structural disruption of normally magnetized bodies as by the effects of magnetic field reversals. North of 58° S the sea floor lies shoaler than in Drake Passage but with rather less small scale roughness. Asymmetric bathymetric scarps, such as are generally typical of fracture zones, occur here but cannot be correlated between profiles. As in eastern Drake Passage, an approximate symmetry can be seen about a roughly centrally situated anomaly and an unambiguous identification of the Magnetic Reversal Time Scale cannot be made.

In the far east Scotia Sea I tentatively identify an active centre spreading at about 2·7 cm/yr/side along

80°, from within a series of short-wavelength high amplitude anomalies. Where seen, the centre coincides with a generally north–south zone of rough topography along 30° W, apparently continuous between the northern arm of the South Sandwich Trench and the west–east fracture zone lying along 61° S[19], and previously thought to be the Mesozoic inner arc postulated by Trendall[20] as a source for tuffaceous greywackes on South Georgia. In the northern part, anomalies are identified out to 7 or 8 m.y. on both sides, which eastward extend to the South Sandwich Islands themselves. Westward, anomalies beyond 8 m.y. have a similar trend, but correlate less well and cannot be identified. The anomalies are

A model based on the data discussed here must be considered provisional and as such I would propose a pole of relative rotation of the South American and Antarctic plates close to 150° W, 72° S, with an equatorial separation rate of 2 cm/yr, principally to be consistent with the calculated spreading close to the South Atlantic triple junction and with movement along the line of the Shackleton Fracture Zone. The model, shown schematically in Fig. 4, also incorporates the small Sandwich plate and, faintly to emphasize that at present it is one of many alternatives, a scheme for the western Scotia Sea.

Plate convergence is implied at the western margin of southern Chile at rates varying between 1·2 and 1·4

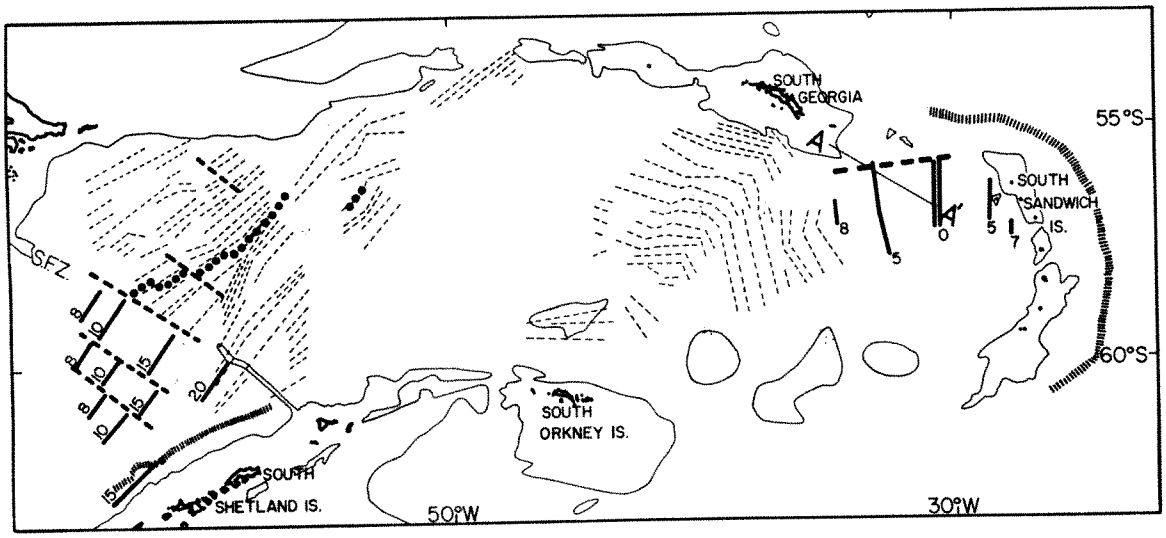

Fig. 2. Magnetic lineations in the Scotia Sea[4]. Dated lineations are shown as thick continuous lines (numbers are ages in m.y.), undated lineations as thin dashed lines. Fracture zones are thick dashed lines (SFZ is Shackleton FZ) and trenches are hatched. Solid circles show the axis of the double bathymetric ridge in the west Scotia Sea and the thin continuous line is the 2,000 m depth contour.

seen on several profiles[4], but no single profile demonstrates all the points made above. For example, profile AA′ of Fig. 3 (located on Fig. 2) compares well with profile EE′ of Eltanin Cruise 19[21] between 0 and 5 m.y. on the western limb of the spreading centre, but westward is affected by a probable fracture zone (marked FZ) and eastward suffers a 90° course alteration.

Present Plate Boundaries and Relative Motion

The major implication of the magnetic lineations for present plate motion concerns this postulated active spreading centre lying to the west of the South Sandwich Islands. With the trench and associated fracture zones it defines a new "Sandwich" lithospheric plate, growing at 2·7 cm/yr at its western margin and overriding Atlantic oceanic crust. The implied age of 7 to 9 m.y. for the crust beneath the islands is consistent with potassium–argon ages of 0·7 and 4·0 m.y. for lavas thought to represent the older parts of the exposed succession[22]. Secondary extensional features are now being found behind many oceanic island arcs[23], so it is probable that the trench formed first, perhaps as a result of a change in the boundaries of the major plates, and that the spreading centre was a secondary development.

The existence of the Sandwich plate removes the requirement that the boundary between the major plates to the west must start from the northern end of the South Sandwich Trench, but the distribution of earthquake epicentres suggests that some relative motion may be occurring along both the northern and southern Scotia Ridge. Bathymetrically, no west–east lineation can be seen along the north Scotia Ridge, whereas a deep, steep-sided trough bisects much of the southern limb. Several epicentres are closely associated with the Shackleton Fracture Zone and others lie to either side between 58° S and 59° S.

cm/yr, approximately along 120°, and at the much greater rate of 5·4 cm/yr at the South Sandwich Trench. Spreading west of the Shackleton Fracture Zone is presumed to have ceased but, to its east within the Scotia Sea, a resultant separation of 1·2 cm/yr must be accommodated by motion at the Drake Passage spreading centre and along the southern Scotia Ridge. If the spreading centre between South Georgia and the South Orkney Islands is real, it does not appear to be active at present.

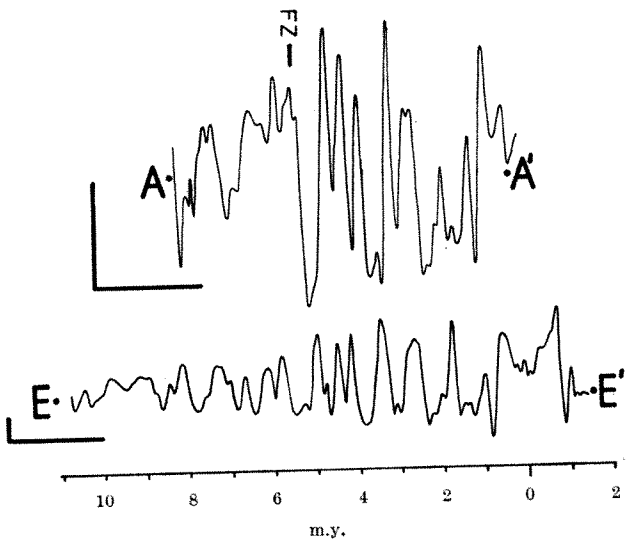

Fig. 3. Magnetic profile AA′, located in Fig. 2, compared with profile EE′ from Eltanin Cruise 19[21]. Position of fracture zone shown (FZ). Vertical and horizontal scale lines represent 250 gamma and 100 kms.

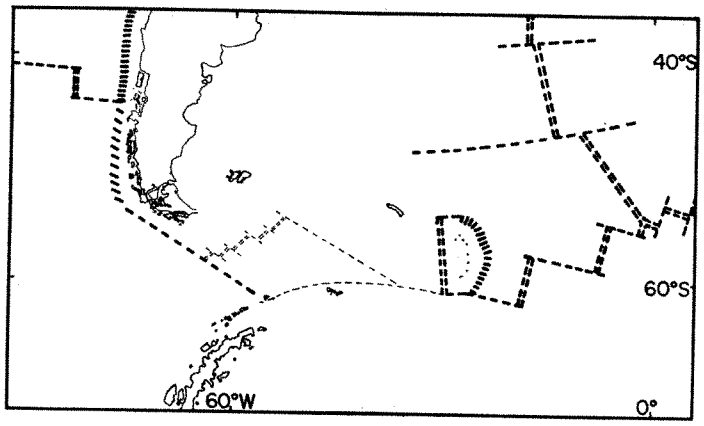

Fig. 4. Postulated boundaries between African, South American, Antarctic and Sandwich plates. Motion between South American and Antarctic plates accords with a pole of rotation close to 150° W, 72° S and an equatorial separation of 2 cm/yr. Plate boundary types are, spreading centre (≡≡≡≡), fracture zone (----) and convergence zone (I I I I). Possible Scotia Sea model is shown faint.

The intense earthquake activity associated with the leading (eastern) edge of the Sandwich plate is attributable in a general sense to the high convergence rate but, more specifically, the 170 km depth to the deepest earthquake is shallower than might be expected[24,25] if plate consumption at 5·4 cm/yr had proceeded for approximately 8 m.y. With this exception, all earthquake activity in the region is seen to occur at boundaries across which relative motion is slow; the lack of activity along other parts of these boundaries may in part result from this slow motion.

Evolution of the Scotia Ridge

The magnetic lineations and recent work on the structure of some of the flat-topped, steep-sided, shallow submarine ridges which make up the Scotia Ridge[3,5–7,26,27] also indicate aspects of the broad structural history of the region. The Ridge abounds with geological structures inconsistent with their present isolated situation and truncated by present "continental" margins, suggesting the fragmentation of a previously continuous continental area. The age of these structures argues a post-Cretaceous fragmentation, which is consistent with the suggested post-Middle Tertiary age for most of the Scotia Sea[4]. Although this latter age is speculative, and parts of the Scotia Ridge have not been examined, sufficient information is available to permit a generalized reconstruction. There is no evidence within the Scotia Sea, east of the Shackleton Fracture Zone, of crustal consumption at northern or southern margins, so that the magnetic lineations of Fig. 2 probably show the true directions of separation of the north and south Scotia Ridge. The indicated reconstruction moves the south Scotia Ridge north-westward along the line of the Shackleton Fracture Zone until Elephant Island lies close to Cape Horn. Simultaneously, South Georgia is moved towards the South Orkney Island block, which with the last movement results in a net westward movement of South Georgia, shortening the north Scotia Ridge. The structure of component blocks of the south Scotia Ridge indicate that it too should be made more compact[5–7], and seemingly the entire Scotia Ridge becomes a continous continental connexion between West Antarctica and South America. The Pacific margin of this block is continuous, cuspate in shape, and comprises only South America as far south as Cape Horn and West Antarctica southward from Elephant Island. Prior to its presumed mid-Tertiary fragmentation this continental area may well have undergone only minor adjustments since the fragmentation of Gondwanaland. If the separation of South America, Africa and East Antarctica has proceeded more or less steadily since their initial break-up it therefore becomes necessary to introduce some relative motion between separate East and West Antarctic plates from then until the Middle Tertiary when, perhaps, these two joined as West Antarctica began to separate from South America. The acceptance of such an initial reconstruction of the Scotia Ridge region and of Mesozoic relative motion between parts of the present Antarctic plate greatly simplifies the problem of Gondwana reconstruction[28,29].

The marine geophysical investigations on which this paper is based are supported by the Natural Environment Research Council. I thank Professor D. H. Griffiths for discussions and, with Dr D. P. Mackenzie, for reviewing the manuscript.

Peculiar Pulse Burst in PSR 1237+25

GENERAL features of the short term variations in pulsars are remarkably steady. It has been found[1], for example, that PSRs 1919+21 and 2016+28 (AP2015) exhibit a marching subpulse phenomenon, and this effect has since been detected in other pulsars. Other pulsars such as PSRs 0950+08 and 1929+10 show no such obvious correlation from pulse to pulse, but do have characteristic statistical properties on the same time-scale. Pulsar 0950+08 is very erratic, often showing 100 per cent modulation of the pulse energy over a single pulse period. On the other hand, 1929+10 has a pulse to pulse modulation of only 50 per cent with the exception of null pulses[2] which recur regularly. Thus the characteristic short-term variations are an additional steady parameter of each pulsar which deserves to be considered along with the period, pulse shape, polarization properties and spectrum as a property of the source. The short-term variations of PSR 1237+25 have been described in detail in two earlier papers[2,3]. This communication describes a peculiar change of mode that occurs infrequently in sequences of pulses from 1237+25.

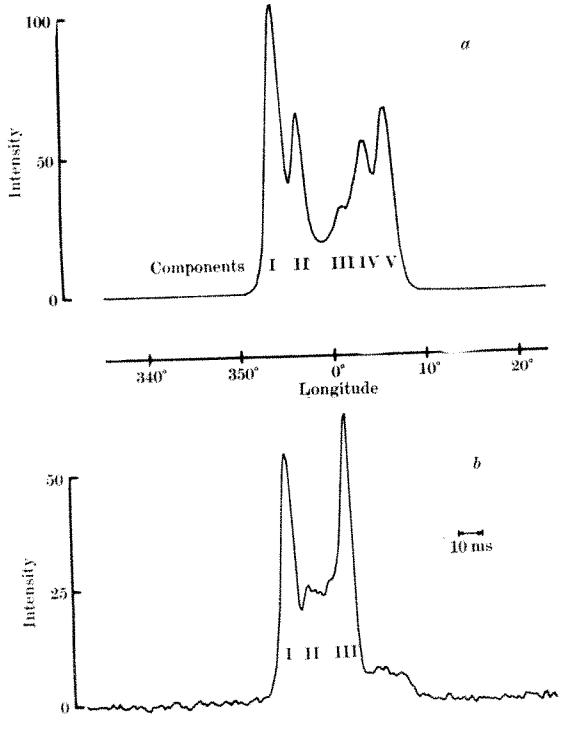

Fig. 1. *a*, A typical average pulse profile from PSR 1237+25 at 318 MHz, showing five distinct components. 1,344 pulses. *b*, The average profile from 45 pulses during the change of mode, showing the weakness then of components IV and V.

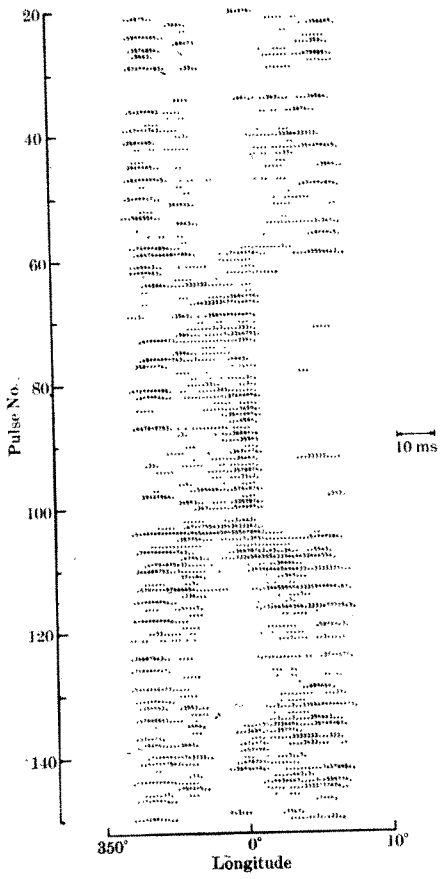

Fig. 2. Computer printout showing an abrupt change of mode at pulse 60 lasting to pulse 104.

It has been shown[3] that the 1237+25 average pulse has five distinct components which comprise two systems of correlated subpulses. Fig. 1*a* contains a typical average pulse profile at 318 MHz which displays these components. Assuming the rotating star model for these objects, the abscissa has been divided into degrees of longitude such that 360° of longitude equals one pulse period and the zero is arbitrary. F. D. Drake has pointed out to me that this longitude is that of the sub-Earth point of the rotating star and may not indicate the relative positions of the radiating regions because of beaming effects. The detailed analysis of a sequence of pulses described in ref. 3 led to the conclusion that components I, II, IV and V participate in a short-period system of subpulse movement, while component III and part of II and IV participate in a long-period system. To confirm these results in the raw data, which are recorded digitally in synchronism with the apparent pulsar period as described in ref. 3, the intensities recorded for a single pulse are scaled and printed by the computer across a single line. Successive pulses are printed on successive lines. An example of this output from an observation of 1237+25 at 318·5 MHz with linear polarization on July 31, 1970, is shown in Fig. 2. An abrupt change of mode occurs at pulse 60 and lasts until pulse 104 where the mode returns to normal just as abruptly. Components IV and V are very weak during this peculiar mode while component III is enhanced considerably. Fig. 1*b* contains the average of these 45 pulses. In both figures it is evident that component III has a very sharp cutoff on the trailing edge.

Similar mode changes have been observed on several occasions. In one case which lasted for about 250 pulses

component II was enhanced while components II and III became much more steady than normal. On another occasion the mode change lasted for about 1,300 pulses. In this case the pulse energies were weak so that detailed information could not be obtained. The phenomenon has been observed at 430 MHz with circular polarization. Mode changes lasting for five to ten pulses have also been detected.

Molecular Oxygen Absorption of Solar Lyman-α observed by Interkosmos-I

THE satellite Interkosmos-1, a joint project of the Soviet Union, the German Democratic Republic and Czechoslovakia, was launched on October 14, 1969, into an orbit with perigee height 260 km, apogee height 640 km and an inclination of 48·4 degrees. A Lyman-α photometer, designed at this institute, was mounted on the observing platform of the satellite, and directed towards the Sun with an accuracy of ±1 degree. The photometer consisted of a modified ionization chamber of Forsterite ceramics with an LiF window and a filling of NO gas[1], followed by a d.c. amplifier with a time constant of 0·14 s and two output channels with different sensitivities. The spectral range of the photometer was from 1050 Å to 1350 Å[2]. Its absolute calibration, carried out at the Physical Institute of the Academy of Sciences of the USSR, yielded a scale value of $K_{phot} = 0{\cdot}780 \times 10^{11}$ photons $cm^{-2}\ s^{-1}\ V^{-1}$ at 1216 Å in the high-sensitivity channel, with an error of ±3 per cent. During the period of observation, October 15–23, 1969, the measured absolute values of solar Lyman-α flux varied between 3·7 and 4·7 ergs $cm^{-2}\ s^{-1}$, with a mean value of 4·1 ergs $cm^{-2}\ s^{-1}$. One purpose of the experiment was to measure the height-dependent absorption of Lyman-α in the upper atmosphere when the satellite entered the Earth's shadow ("satellite sunset"). The most reliable data of this kind were obtained on October 15 at 1409 UT, when the line-of-sight between the satellite and the Sun touched the Earth's surface at a geographic latitude of about 40° N. For this case, Lyman-α absorption, expressed in terms of optical thickness of the atmosphere as a function of the "grazing height" above the Earth's surface, is presented in Fig. 1. The orientation of the satellite towards the Sun was guaranteed for all grazing heights greater than 10 km.

Theoretical curves of optical thickness at grazing incidence were calculated from the O_2 and N_2 densities given by the CIRA 1965 model atmosphere, which are nearly equal to the mean values between the summer and winter models of the US Standard Atmosphere Supplement 1966. Absorption cross-sections of $\sigma(O_2) = 8{\cdot}4 \times 10^{-21}$ cm^2 for O_2, and $\sigma(N_2) = 6 \times 10^{-23}$ cm^2 for N_2 (ref. 3) were adopted. With these cross-sections, absorption by N_2 contributes less than 3 per cent to the total optical thickness below 120 km. This theoretical height dependence of optical thickness, taking into account the finite diameter of the Sun's disk, is represented by the

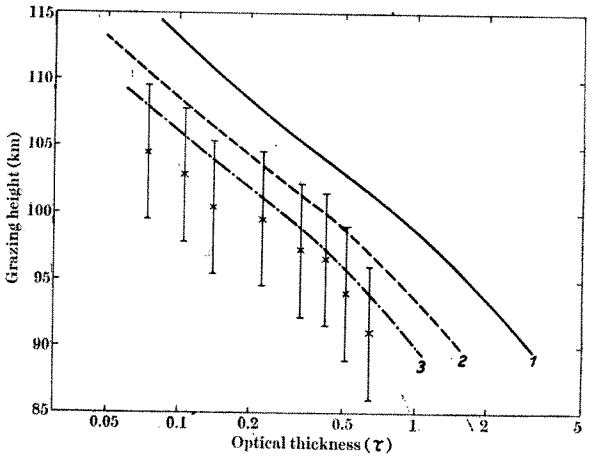

Fig. 1. Optical thickness at grazing incidence for Lyman-α, measured on the satellite (crosses). Theoretical values of optical thickness are computed from the CIRA 1965 model atmosphere (curve 1), and with O_2 densities reduced to a half and a third of the CIRA values (curves 2 and 3, respectively).

continuous curve in Fig. 1. It coincides almost exactly with similar calculations by Thomas and Bowman[4]. Fig. 1 shows that the measured data have nearly the same height gradient as the theoretical curve, but their absolute values are smaller than the theoretical ones by a factor of three or more.

Because it seems improbable that the cross-sections adopted are wrong by a factor of this order of magnitude, we have to conclude that at least in the height interval between 90 and 120 km the O_2 concentration should be only one third of the CIRA model values in order to fit the observed absorption. (The broken curves indicate theoretical optical thickness if the O_2 concentration is reduced to half or one third of the CIRA values, respectively.) This conclusion agrees well with recent rocket absorption measurements around 1450 Å made by Wildman *et al.*[5] in Australia, and with a similar difference between CIRA data and rocket ultraviolet absorption results reported by Weeks and Smith[6]. Mass spectrometer data[7] also indicate that at around 150 km the CIRA O_2 concentrations are considerably too large, whereas the analysis of Solrad-8 Lyman-α absorption by Norton and Warneck[8] seemed to agree with the CIRA model. It must be remembered, however, that the calculation of grazing heights for satellites is difficult and may introduce systematic errors. In the case of our measurements, the grazing heights were determined from simultaneous intensity records of visible sunlight on the satellite, and the estimated height error should not exceed ±5 km, as indicated by error bars in Fig. 1. The observed difference, therefore, between the O_2 concentration of the CIRA 1965 model and our data seems to be significant.

Size Distribution of Lunar Soil

When Duke *et al.*[1] measured the size of lunar soil returned by Apollo 11, they found a size distribution similar to that of glacial till and other terrestrial soil, except that the lunar soil is noticeably deficient in material finer than 15 μm. They feel that a partial explanation for this deficiency is that it is caused by melting and consequent consolidation into clumps of finer particles on the Moon. We wish to suggest another partial explanation, derived from wear theory—it is that the finer particles are missing in lunar soil because materials in a lunar environment have a higher surface energy.

Particles produced by wear during sliding have a diameter, d, given by a relationship which can be expressed most simply as

$$d = 60{,}000\ W_{ab}/p \qquad (1)$$

where W_{ab} is the surface energy of adhesion of the two rubbing bodies a and b, and p is the penetration hardness (Vickers or Knoop) of the body from which the particle is formed[2]. The theoretical basis for this relationship is an energy balance between the surface energy of a contact and the volume elastic energy of the material in the vicinity of a contact. The same equation gives the least size of particles formed by attrition during ball milling[3], and it is possible that it also governs lunar attritious processes.

For typical rock materials on the Moon, p is about 600 kg/mm², and for a pair of such materials *in vacuo* W_{ab} can be estimated to be 1,000 erg/cm². Thus d in equation (1) has a value of 10 μm, in good agreement with the observed value.

In a terrestrial dry air environment, W_{ab} is reduced by about a factor of two from the value I have given, while in a high humidity environment or in the presence of liquid water, further substantial reductions in W_{ab} take place. Corresponding reductions can be anticipated in the least sizes of particles formed on Earth by attritious processes.

Coupling between Aerials used for measuring Ionospheric Drifts

An important consideration when designing an array of aerials to sample the diffraction pattern of a radio wave reflected from the ionosphere is to ensure that the results are not affected by mutual coupling. Signals reradiated from one aerial may be received by another, and this could affect the measured characteristics of the diffraction pattern. Any subsequent measurements (for example, of ionospheric drifts) would also be affected.

A simple check for the effects of such coupling is to look for differences in the cross correlation between records from different aerials. If coupling is important, the values of the cross correlation at zero shift between separated aerials may be expected to show consistent differences depending on their relative orientation. In particular, it may be expected that the correlation for aerials aligned parallel to each other may be different from the correlation for aerials which are mutually perpendicular, and that this effect should be greater for smaller separations.

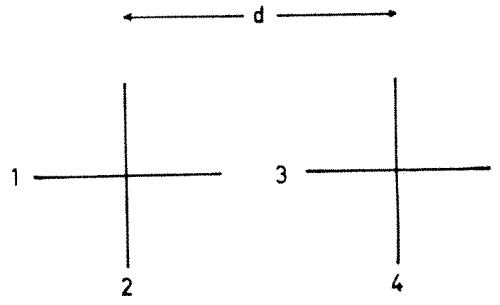

Fig. 1. The aerial configuration.

Such an experiment was carried out using the array of 178 dipole aerials at Buckland Park near Adelaide, South Australia[1]. Pairs of mutually orthogonal half wavelength dipoles (1·98 MHz) with their centres at the same pole were chosen from within the array as shown in Fig. 1. Separate receivers and a four channel pen recorder were used to record the amplitude fluctuations of circularly polarized radio waves reflected from the ionosphere at vertical incidence. From the four records obtained the cross correlation at zero shift for each of the six possible combinations was calculated. Two of these values represent the correlation between signals obtained by orthogonal dipoles at the same site (ρ_{12}, ρ_{34}), two represent the correlation between separated orthogonal dipoles (ρ_{14}, ρ_{23}), one the correlation between dipoles aligned end to end (ρ_{13}) and one represents the correlation between dipoles parallel to each other (ρ_{24}).

The effects are most likely to be seen when the correlation between the fading at adjacent dipoles is low. Partial reflexions from near 95 km were therefore used as these have been observed to give the smallest pattern scale among echoes returned from the ionosphere. In order to eliminate any possible effects due to the receivers or recording apparatus, the connexions between each dipole and the receiver/pen recorder combination were rotated between each record. The records were digitized using eighty levels.

95 km echo. March 3, 1970.

The results for twenty-five records representing three different separations (d) between the crossed dipoles are given in Table 1. Each record is identified by a time, and each value of cross correlation is listed in the appropriate column. The variations with time do not represent

errors of measurement but real variations in pattern scale from one occasion to another. The values were averaged, as shown in Table 1, to look for any systematic differences between the pairs.

It can be seen that the absolute value of the cross correlation decreases with increasing separation as would be expected because of the random nature of the irregularities in the diffraction pattern. The difference between cross correlation values for dipoles the same distance apart but differently oriented with respect to one another is, however, small. This implies that coupling between any pair of separated dipoles has a negligible effect on the measured correlation even for the minimum separation of 91 m.

It has been suggested[2] that errors in the true velocity derived from full correlation analysis[3,4] may be a consequence of the depression of the measured cross correlation values from their true value especially when the correlation is high, as will be the case for closely spaced aerials. The above results suggest that this depression is not caused by aerial coupling. Experimental factors such as receiver differences or digitizing errors must therefore be responsible. This is confirmed in these experiments, which show that the cross correlation values at zero shift between orthogonal dipoles at the same location (ρ_{12} and ρ_{34}) are not unity, as might be expected, but have an average value of 0·92. The reasons for the experimental factors which cause this effect are at present being investigated.

I thank Dr B. H. Briggs for his advice and encouragement. The work was supported by the US Air Force Office for Scientific Research, the Australian Research Grants Committee and the Radio Research Board (Australia).

BIOLOGICAL SCIENCES

Phosphorylation of D-Arabinosyl Adenine by *Plasmodium berghei* and its Partial Protection of Mice against Malaria

9-β-D-arabinofuranosyladenine (ara-A) is a nucleoside antibiotic (Fig. 1) with a broad spectrum of activity against animal viruses[1–7] and little or no toxicity when administered parenterally to animals. The LD_{50} for an intraperitoneal injection is 4,677 mg/kg[7]. The rodent

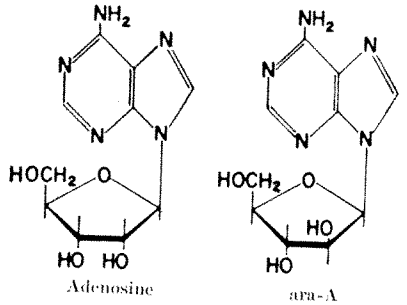

Fig. 1. Structure of 9-β-arabinofuranosyladenine (ara-A).

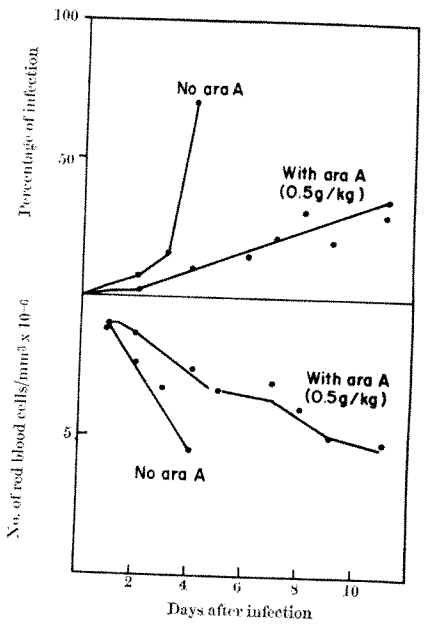

Fig. 2. Effect of ara-A on the course of infection of *P. berghei* in mice. *P. berghei* was maintained according to Wellde *et al.*[12]. Mice were injected intraperitoneally with 2×10^7 parasitized red blood cells per mouse. One group (ten mice per group) also received a daily injection of 0·5 ml. of saline containing 0·5 g/kg of ara-A. The mice which had not received the drug all died within 5 days after infection. Mice treated with drug remained alive from 10–14 days after infection. The number of red blood cells and of parasitized red blood cells was determined from blood removed from the tail.

malarial parasite, *Plasmodium berghei*, resembles viruses in that it is an intracellular parasite. Moreover, the host is protected by interferon[8]. There is evidence that *P. berghei* utilizes part of the host protein synthesizing system[9,10].

We have studied the effect of a daily dose of 0·5 g/kg of ara-A on infection of mice with *P. berghei* and found that the percentage of infected red blood cells was lower than in control animals (Fig. 2) which had been infected but not treated with the drug and that the development of anaemia was significantly slower in infected mice which had received ara-A. Moreover, drug treated animals remained alive twice as long as control animals.

Enzymes involved in nucleic acid biosynthesis are specific for the configuration of the 2′ pentose carbon of nucleotides. This is well documented for RNA and DNA polymerases. The effect of ara-A on *P. berghei* may reflect lack of ability of malarial enzymes to distinguish the "wrong" configuration. If malarial adenosine kinase "mistakenly" phosphorylates the drug, ara-A nucleotides will be formed. Ara-ATP is a competitive inhibitor of mammalian DNA polymerase *in vitro*[11].

^{3}H-ara-A was prepared[11] and 20 μCi (specific activity 4·81 mCi/mmole) together with 450 μCi of $^{32}P_i$ were injected in 0·1 ml. saline into each mouse three days after malarial infection (ten mice per group). Blood was collected 20 h later by heart puncture and livers were removed. Preliminary experiments indicated that uninfected blood could not phosphorylate ara-A. Free parasites were isolated in 10 ml. of distilled water containing 1 g of glass beads (200 μM in diameter) and homogenized in a Sorval 'Omni-mixer' for 5 min at speed control No. 5. 10 ml. of cold 10 per cent trichloroacetic acid (TCA) were added followed by 40 ml. of cold 5 per cent TCA. The mixture was centrifuged for 10 min at 15,000*g* at 4° C. Supernatant fluid was collected. The precipitate was washed with 20 ml. of 5 per cent of cold TCA. The combined TCA soluble extract was washed five times with three volumes of ether to remove TCA and applied on a 2·4 × 20 cm Dowex 1–8X column (200–400 mesh, chloride form). Preliminary experiments

showed two peaks in the elution with 5 mM HCl. The first represents nucleotide monophosphate, the second nucleotide di and triphosphate which are inseparable in these conditions. Nonphosphorylated ara-A was washed from the column with water and phosphorylated product was eluted with 5 mM HCl (Fig. 3). Only traces of ^{3}H-ara-A were present. Most of the nucleosides were phosphorylated to the di and triphosphates (second peak of ^{32}P marker). Further examination showed most of the material was ara-ATP. Phosphorylation of ^{3}H-ara-A by infected and control (non-infected) mouse liver was followed by the same procedure except that homogenization was carried out in 0·9 per cent saline without glass beads. In both controls (Fig. 4*A*) and infected livers (Fig. 4*B*) ^{3}H-ara-A was non-phosphorylated and eluted from the column with water. A very small amount of phosphorylated ara-A eluted with 5 mM HCl. A slight phosphorylation appeared in ara-AMP (first peak of the ^{32}P marker). No tritiated product appeared in the position representing nucleotide di and triphosphate (second peak of ^{32}P marker).

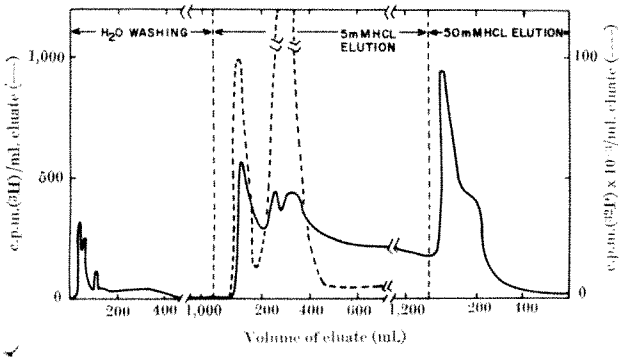

Fig. 3. Elution profile on a Dowex column of phosphorylated ara-A extracted from *P. berghei*. Mice infected with *P. berghei* were injected with ^{3}H-ara-A and ^{32}P$_{i}$. After 20 h incubation, free parasites were isolated and the acid soluble fraction obtained from the parasites was applied on a Dowex 1–8X column. Unphosphorylated ^{3}H-ara-A was washed off the column with water and the phosphorylated products were eluted with 5 mM HCl. The experimental details are described in the text. ———, ^{3}H/ml. eluate; - - - -, ^{32}P/ml. eluate.

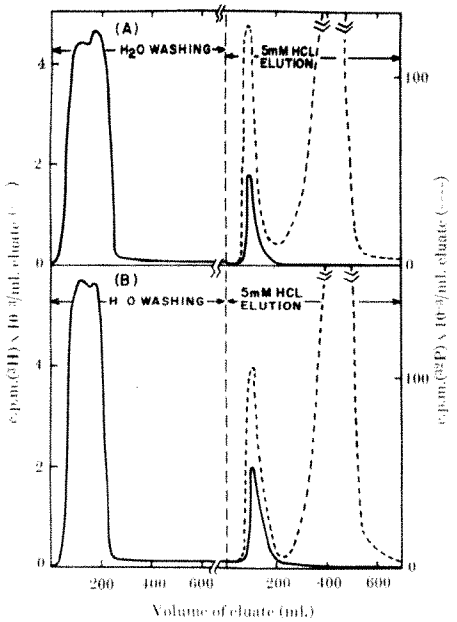

Fig. 4. Elution profile of phosphorylated ^{3}H-ara-A in the acid soluble fraction of mouse liver. Experimental conditions are described in the text. ———, ^{3}H/ml. eluate; - - - -, ^{32}P/ml. eluate. *A*, acid soluble fraction from uninfected mouse liver; *B*, acid soluble fraction from infected mouse liver.

Normal mouse liver accumulated 46 nmoles of ^{3}H-ara-A and its phosphorylated product per g fresh liver. Of this, only 5·3 nmoles (11·5 per cent) were ara-AMP. Infected mouse liver accumulated 100 nmoles of ^{3}H-ara-A and its derivative of which 18 nmoles were ara-AMP (17·8 per cent) per g fresh liver. *P. berghei*, however, accumulated 813 nmoles of ^{3}H-ara-A and its derivatives per g fresh tissue. 755 nmoles (93 per cent) were phosphorylated mostly to di and triphosphate.

P. berghei can efficiently accumulate and phosphorylate ara-A to ara-ADP and ara-ATP. We have evidence (unpublished) that *in vitro* ara-ATP is a competitive inhibitor of ATP for leucyl-tRNA synthetase obtained from a tryparosomatid. It is possible that inhibition of development of malaria by ara-A is directly related to the parasite's ability to phosphorylate D-arabinosyladenine to ara-ATP which then serves as a competitive inhibitor of ATP for essential enzyme systems. On the other hand, the mammalian host has little capacity to accumulate and phosphorylate ara-A. Moreover, phosphorylation is halted at the ara-AMP level.

Effects of Lithium and of *p*H on Synaptosomal Metabolism of Noradrenaline

CURRENT hypotheses about mania and depression are that they correspond to greater or lesser availability of catecholamines at central synapses[1], or to changes in electrolyte and water distribution[2]. The mode of action of lithium salts, which seem to be effective at least in mania, has been related to both hypotheses[3]. There are several findings regarding catecholamine metabolism. They include a disappearance of brain noradrenaline after inhibition of tyrosine hydroxylase which is more rapid following Li^{+} treatment[4]; a shift in brain metabolism of noradrenaline from extracellular methylation (by catechol-O-methyl transferase), toward intraneuronal deamination (by monoamine oxidase)[5]; and a decreased rate of release of ^{3}H-noradrenaline during electrical stimulation of brain slices *in vitro*[6]. Evidence regarding effects of Li^{+} on active uptake of noradrenaline into neurones, a major means of inactivation of catecholamine released at syn-

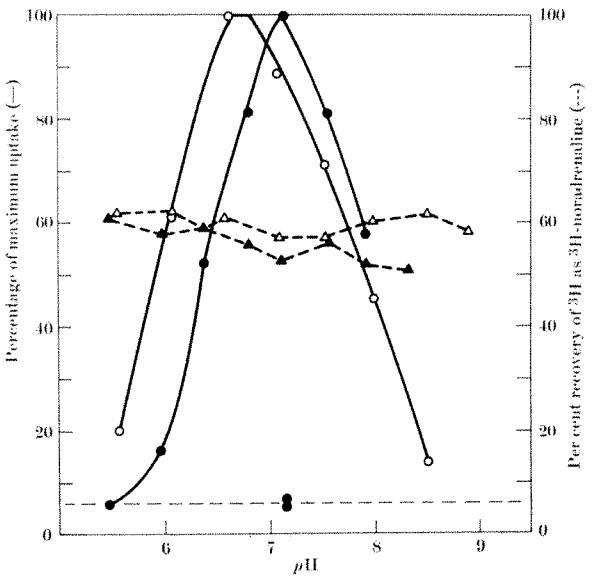

Fig. 1. Rat brain synaptosomal uptake of ^{3}H-noradrenaline as a function of *p*H in two physiological media. Two independent buffer systems were used: *tris*-(hydroxymethyl)-aminomethane-phosphate (○—○), or N-2-hydroxyethylpiperazine-N′-2-ethane-sulphonic acid (●—●) (California Biochem. Co.), with physiological concentrations of Na^+ (including NaOH used for titration), K^+, Mg^{2+}, and added glucose and ascorbate. Uptake blanks (● - - - ●) represent determination at 4° C, or at 37° C with boiled tissue. △ - - - △, Tris-phosphate recovery; ▲ - - - ▲, N-2-hydroxyethylpiperazine-N′-2-ethane-sulphonic acid recovery.

apses, is somewhat in conflict. One study[7] reported enhanced uptake *in vitro* of ^{3}H-noradrenaline into synaptosomes ("pinched-off nerve endings") prepared after the administration of large amounts of unneutralized Li_2CO_3. This finding has not been confirmed, and there is evidence that uptake of ^{3}H-noradrenaline into intact brain[5], or brain slices[6], may not be altered by prior treatment of rats with LiCl. Thus questions arise as to the effect of carbonate ion or *p*H on amine uptake. These findings, together, suggest that lithium may tend to keep noradrenaline in a pre-synaptic location, while increasing catabolism, particularly by oxidative deamination. The net effect would be decreased availability of this putative transmitter at central synapses, an interpretation consistent with the antimanic effects of lithium.

The effects of lithium on amine uptake, however, seemed to require further study. Rats were therefore given solutions of Li_2CO_3. Equal volumes of distilled water (which did not significantly alter uptake), or gastric intubation alone, were used in controls. All rats were given two to three divided daily doses by oro-gastric intubation for 3–5 days. Consistent $[Li^+]$ of 1 mequiv/l. of serum or 0·5 mequiv/kg of wet brain were found by flame photometry at a daily dose of 200–300 mg Li_2CO_3/kg body

Table 1. EFFECT OF LITHIUM *in vivo* ON RAT BRAIN SYNAPTOSOMAL UPTAKE OF ^{3}H-NORADRENALINE *in vitro*

Treatment	Mean per cent of control uptake*	s.e.	*N*	*P*
Li_2CO_3 300 mg/kg	108·3	±11·6	9 rats	NS
			18 assays	NS
Li_2CO_3/HCl, *p*H 7, 300 mg/kg	109·7	±5·7	9 rats	NS
			17 assays	< 0·02

Synaptosomal fractions[8] were transferred from sucrose gradients to tubes containing Krebs-bicarbonate medium[9] with $2–3 \times 10^{-8}$ M ^{3}H-noradrenaline (dl-NA-7-^{3}H, 9 c/mmole, New England Nuclear Corp.) incubated in air at 37°. Aliquots of the mixture were taken for protein determination[10], and tubes were centrifuged at 48,000*g* for 30 min. Perchloric acid preparations of supernatant medium and the synaptosomal pellet were chromatographed on alumina columns[11]. Total ^{3}H and ^{3}H-noradrenaline radioactivity were assayed[12]. "Uptake ratios", defined as: nCi ^{3}H-noradrenaline per gm synaptosomal protein ÷ nCi ^{3}H-noradrenaline per ml. incubation medium, were calculated. The mean uptake ratio for all untreated tissues was 918·2 (±62·2, s.e.m.). Experiments included controls with each experimental group; results are expressed here as per cent of control; statistics were done as *t*-tests of paired differences.

weight (6–8 mequiv Li^+/kg). Such doses of carbona solution (*p*H 11) were grossly toxic and often fatal. Tl treatment of rats with alkaline Li_2CO_3 solutions resulte (Table 1) in a small (8 per cent) insignificant increase ^{3}H-noradrenaline uptake by isolated brain synaptosome with marked individual variations. The addition of L ion *in vitro* at 4 mequiv/l. led to a significant decrease ^{3}H-noradrenaline uptake by synaptosomes from norm rats, and even greater decrease at 10 mequiv./l., where additional Na^+ (4 mequiv/l. above normal) had no signil cant effect on uptake *in vitro* (Table 2).

Table 2. EFFECT OF LITHIUM ON RAT BRAIN SYNAPTOSOMAL UPTAKE ^{3}H-NORADRENALINE *in vitro*

Ion	Concentration (mequiv/l.)	Mean per cent of control uptake	s.e.	*N*	*P*
Li^+	4	88·9	±3·9	8	< 0·05
	10	83·2	±1·5	6	< 0·00
Na^+	4	96·0	±5·2	8	NS

Either Li^+ as a neutralized bicarbonate–chloride salt, or NaCl, was add directly to the incubation medium, and *p*H readjusted, before uptake.

The effects of *p*H on uptake (Fig. 1) were striking, wit maximum uptake at approximately *p*H 6·8, and marke decreases toward minima approaching uptake "blanks" Recovery of total tissue tritium as ^{3}H-noradrenaline b column chromatography[11] remained constant at each *p*H suggesting that decreased uptake was not an artefact noradrenaline destruction.

Because of the gross toxicity of alkaline Li_2CO_3 ar the marked effect of *p*H on noradrenaline uptake *in vitr* rats were also treated with neutralized Li_2CO_3/H solutions, which were relatively well tolerated. Agai an apparent small (10 per cent) but less variable increa in synaptosomal uptake of ^{3}H-noradrenaline *in vitro* w noted. It was not significant at an *N* of nine rats, b attained a $P < 0·02$ at an *N* of 17 *in vitro* assays (Table 1

In other experiments, enzyme assays *in vitro* reveale no changes in activity[13] of monoamine oxidase prepare from beef renal cortex mitochondria[14] by additions Li^+, K^+ or Na^+ in the range of 0·3–8·3 mequiv/l., and changes in catechol-O-methyl transferase activity of soluble supernatant fraction of rat brain[15] added to medium with 4 mequiv Li^+/l. Furthermore, estimates rates of glucose oxidation by measurements of ^{14}C produced from labelled glucose[16] by mitochondria synaptosomal fractions of rat brain[8] showed an insigni cant small decrease in the presence of 4 mequiv Li^+/l.

The apparent enhancement of synaptosomal uptake noradrenaline *in vitro* by lithium, while small and questionable significance, is in the direction reporte previously by Colburn *et al.*[7]. The basis of this effect is n clear, although any mechanism proposed should inclu changes which persist through the synaptosomal prepar tion steps. It should therefore be noted that whi alkalotic effects of carbonate administration might expected to decrease uptake *in vivo*, the amount of alkali anion carried into the *in vitro* assay was not sufficient alter *p*H. Furthermore, most of the Li^+ present in bra after treatment is removed during the preparation synaptosomes. Estimates were made of $[Li^+]$ in synapt somes exposed to 4 mequiv Li^+/l. *in vitro*, or followi administration of 8 mequiv Li^+/kg per day for 3 day Suspended synaptosomes were centrifuged and pellet L contents were measured: in these studies, $[Li^+]$ w 2×10^{-4} mequiv/mg protein (about 3 mequiv/l. of syna tosomal water, assuming the synaptosomal pellet ma was 60 per cent water) after *in vitro* exposure to Li^+, b only 4×10^{-6} mequiv/mg protein (about 0·07 mequiv/ after *in vivo* treatment. It is conceivable that Li^+ pr duces alterations of intraneuronal $[Na^+]$ or $[K^+]$ *in viv* which survive synaptosomal preparation and which mig secondarily affect amine uptake[19–21]. The mechanis involved in altered uptake does not seem to include t alteration of activities of enzymes which catabolis noradrenaline or decreased energy supplies from gluco oxidation.

Another important question is whether current comparisons of lithium salt regimens in animals and in man are justified. It has been commonly assumed that animal doses should correspond to therapeutic human doses, producing serum [Li^+] in the range of 0·5–2·0 mequiv/l. In rats, however[4], daily doses (4–8 mequiv Li^+/kg) which produce serum [Li^+] around 1 mequiv/l. are 10 to 20 times larger than those required in patients[17] (0·3–0·5 mequiv/kg) and, as the carbonate salt, are highly toxic to rats. At even lower doses (1–4 mequiv Li^+/kg), lithium carbonate or chloride salts produce severe renal tubular and mitochondrial damage in the rat similar to that seen in heavy metal poisoning[18].

Evidence that the Area Postrema mediates the Central Cardiovascular Response to Angiotensin II

Angiotensin can affect the cardiovascular system in several different ways. Its direct vasoconstrictor action is well recognized but it can also exert cardiovascular effects by stimulating the autonomic nervous system at a variety of sites including the adrenal medulla[1], the sympathetic ganglia[2], the post-ganglionic sympathetic nerve terminals[3] and the brain[4]. It has not been possible, so far, to quantitate the relative importance of these various effects of the hormone in either physiological or pathological circumstances.

We have been particularly interested in those autonomic effects of angiotensin which are mediated by the brain. Vertebral artery infusion of angiotensin in the anaesthetized greyhound causes withdrawal of vagal tone to the heart and results in significant increases of heart rate, cardiac output and blood pressure[5]. This specific response

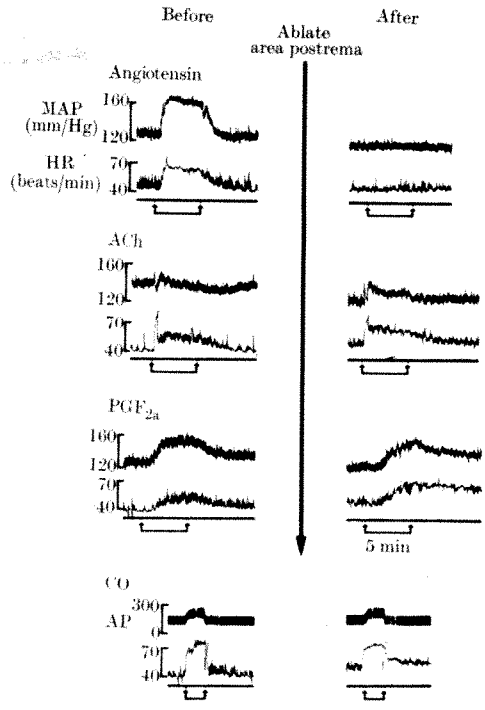

Fig. 1. The effect of ablation of the area postrema on the responses of mean arterial pressure (MAP) and heart rate (HR) to vertebral arterial infusions of angiotensin (1 ng/kg/min), acetylcholine (ACh) (10 μg/kg/min), and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) (8 ng/kg/min). Ablation of the area postrema completely abolished the response to angiotensin while the responses to the other procedures remained. CO, carotid occlusion.

can be demonstrated with vertebral artery infusion rates as low as 0·25 to 1·0 ng/kg/min which result in local blood concentrations ranging from 0·2 to 0·8 ng/ml. (ref. 6). We have shown that this response is due to an action of angiotensin in the caudal half of the medulla[7]. The area postrema lies in this region and is a known gap in the blood–brain barrier[8,9] which might allow angiotensin to reach the brain. Its histological appearance has led some workers to suggest that it is a chemoreceptor zone[10,11], responding to compounds in the bloodstream such as cardiac glycosides[12]. The area postrema lies in an accessible part of the caudal medulla, protruding into the fourth ventricle, and we have therefore studied whether its ablation alters the central effects of angiotensin.

We carried out experiments in nine greyhounds, anaesthetized with chloralose (100 mg/kg), after premedication with morphine (2 mg/kg) intravenously. Arterial pressure and heart rate were recorded by standard techniques using a Statham pressure transducer and Grass polygraph. Infusions into the vertebral artery were given through a polythene catheter through the side wall, without obstructing the flow. The opposite vertebral artery was clamped. All infusions of drugs were preceded and followed by control infusions of saline.

Bilateral ablation of the area postrema by thermocoagulation did not alter the baseline blood pressure or heart rate significantly, but abolished the response to intravertebral infusions of angiotensin. To verify that this was a specific effect we induced autonomically mediated cardiovascular effects by three other procedures: intravertebral infusions of acetylcholine[13] and prostaglandin $F_{2\alpha}$[14], and bilateral occlusion of the common carotid arteries. The autonomic responses to these other stimuli were not affected by ablation of the area postrema. Fig. 1 illustrates a sample experiment and Fig. 2 shows the pooled results of all the experiments.

These results show that the central effects of blood-born angiotensin in low concentrations are dependent on the

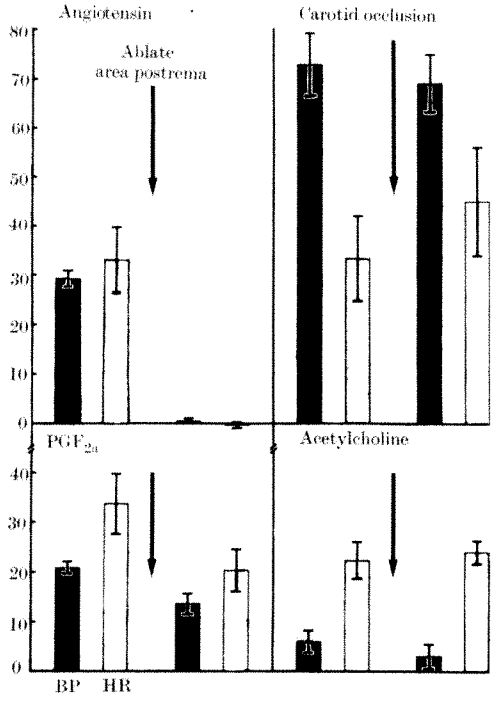

Fig. 2. Summary of the effects of ablating the area postrema in nine dogs. The histograms represent the mean responses of blood pressure (b.p., mm/Hg) and heart rate (h.r., beats/min). The bars represent one standard error on either side of the mean. Ablation of the area postrema abolished the response to intravertebral infusions of angiotensin but the responses to carotid occlusion, $PGF_{2\alpha}$ and acetylcholine remained.

integrity of the area postrema or immediately adjacent tissue. Because ablation of the area postrema neither changes the resting heart rate nor abolishes several other central autonomic effects, it seems likely that the area is relatively specific for angiotensin. Ablation of this area should provide a useful tool for studying the importance of the central effects of angiotensin in various physiological or pathological situations, for example in the response to severe haemorrhage or in chronic renal hypertension.

Note added in proof. Following submission of this work for publication, S. Katayama and H. Ueda have reported that local micro-injection of angiotensin into the region of the area postrema of the cat produces a pressor response (personal communication).

Our thanks are due to Dr M. W. B. Bradbury for helpful advice.

Stimulation of Proliferation of 19S Antibody-forming Cells in the Spleens of Immunized Guinea-pigs after Exchange Transfusion

THERE is abundant evidence that the immune response, both primary (19S) and secondary (7S), is regulated by a feed-back mechanism involving serum antibody, particularly 7S antibody[1–4], but the exact mechanism remains unclear.

Rowley and Fitch[5] found that the primary immune response could be prevented if normal mouse spleen cells were mixed with specific antibody before transfer into irradiated and specifically immunized mice. This suggested that antibody had a direct suppressive effect on the antibody-forming cells. Möller[6], using the plaque technique to enumerate antibody-forming cells, demonstrated that spleen cells already making 7S antibody would give rise to increased numbers of 7S antibody-forming cells when transferred into a previously immunized irradiated animal. In other words, placing antibody-forming cells in an environment free of antibody resulted in their proliferation. *In vitro* studies by Pierce[7] led him to conclude that specific antibody inhibits the primary immune response by combining with antigen and interfering with the macrophage-dependent inductive phase.

Because passive administration of antibody, irradiation of host animals and *in vitro* studies introduce variables which are at times difficult to control or interpret, we have removed serum antibody from immunized animals by exchange transfusion in an attempt to evaluate the effect of endogenously produced antibody on the proliferation of 19S antibody-forming cells in the spleen. We conclude that serum antibody has a direct suppressive effect on the proliferation of 19S antibody-producing cells in the spleen.

Table 1. PRIMARY AND SECONDARY RESPONSE OF RATS AGAINST HEN ERYTHROCYTES

	Mean titre of agglutinins in saline	Mean titre of agglutinins in 'Dextran'
Control group (15 rats)		
Primary response	1/16 (1/4–1/128)*	1/512 (1/32–1/1,024)
Secondary response	1/32 (1/4–1/128)	1/1,024 (1/64–1/2,048)
α-Globulin treated group (10 rats)		
Primary response	— (0–1/2)	1/16 (1/2–1/64)
Secondary response	1/8 (1/2–1/32)	1/256 (1/32–1/512)

* Numbers in parentheses indicate lowest and highest titres obtained.

Hartley strain guinea-pigs (300–500 g) were immunized intravenously with 2×10^8 sheep red blood cells. In one group of animals, 6–22 days after immunization, 40 ml. of blood from unimmunized guinea-pigs was gradually exchanged for the immunized guinea-pigs' blood in 6–7 ml. increments over a period of 30 min or less. The titre of antibody in pre-exchange serum and serum immediately after exchange transfusion, as determined by haemagglutination of a 1 per cent suspension of sheep red blood cells in phosphate-buffered saline, *p*H 7·4, differed by one to sixteen-fold.

Two to four days after exchange transfusion, the animals were killed, their spleens removed and the number of 19S antibody-forming cells determined by the direct plaque technique[8]. Immunized but unexchanged guinea-pigs sacrificed at comparable intervals after immunization comprised the control group. The results are shown in Fig. 1. Each bar represents a single animal. The number of plaque-forming cells in the unexchanged animals reached a peak after 5 days and rapidly declined. Animals exchange-transfused 2–4 days before sacrifice had from three–ten times as many plaque-forming cells as comparable unexchanged animals.

The results of these studies indicate that removal of serum antibody by exchange transfusion from 6–22 days

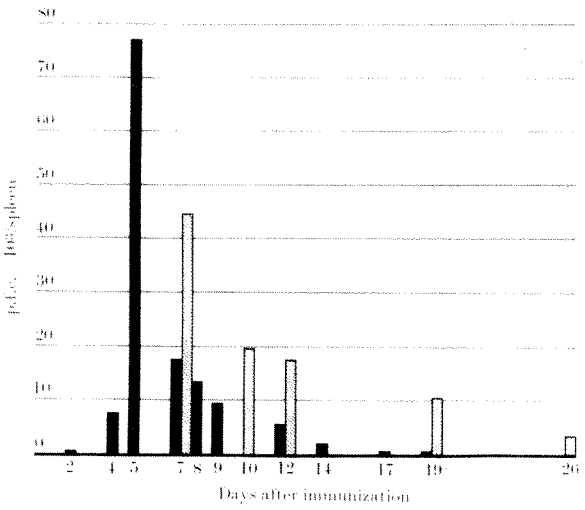

Fig. 1. Black columns, unexchanged; hatched columns, exchange transfusion.

after immunization causes an increase over the expected number of direct plaque-forming (19S antibody-producing) cells in the spleen and supports the concept of a direct feed-back control of the proliferation of 19S antibody-producing cells.

Embryonic Mouse Peripheral Blood Colony-forming Units

HAEMOPOIETIC stem cells, characterized by their ability to differentiate and reproduce themselves, are believed to be precursors of all differentiated blood cells in the organism. During embryogenesis, they are presumably present in the yolk sac, liver, spleen and marrow—the successive sites of erythropoiesis. The stem cells may be derived from a common source or they may arise independently in each site during development. If they are not indigenous to the erythropoietic organ they may be either transported from one site to another through the peripheral blood[1] or incorporated into the developing organ in tissues shared by the previous erythroid site[2,3].

Cells with the characteristics of stem cells can be detected by the spleen colony technique[4]. Spleen colonies derived from stem cells either isolated from[5] or migrating in[6] the peripheral blood have been detected. Spleen colonies found after inoculation of embryonic peripheral blood into lethally irradiated CBA/H (ref. 7) and C57BL/6J mice suggest the possibility that stem cells use this route during development to migrate to successive sites of erythropoiesis.

All C57BL/6J mice used as donors and recipients were obtained from the Jackson Laboratory. Hormonally primed C57BL/6J females[8], mated to C57BL/6J males, were considered to be at zero day of pregnancy on the day when a copulation plug was found. Each donor (12, 14, 16, or 18 day embryo or newborn mouse) was placed in a Petri dish containing 1 ml. of a 1:1 mixture of ice-cold phosphate buffered saline[9] and 1 per cent heparin. They were decapitated and allowed to bleed freely. Blood cell number was determined by counting 0·1 ml. of blood diluted to 50 ml. with 0·9 per cent saline with a Coulter counter model B. The total number of blood cells in an embryo was determined by multiplying cell counts per ml. by the total number of millilitres of blood plus diluent. The volume of blood cell suspension remaining after counting was measured and injected intravenously less than 1 h after collection into lethally irradiated female recipients[10]. Survivors were killed 10 days later and the macroscopic colonies counted.

Table 1. NUMBER OF COLONY FORMING UNITS IN FOETAL AND NEWBORN BLOOD

Days gestation	Total CFU/embryo	Approximate No. of blood cell × 10^7 per embryo	Standard ± error	CFU/10^7 blood cells
12	4·56	0·6	0·01	7·60
14	1·49	1·4	0·06	1·06
16	1·66	11·6	0·47	0·14
18	2·32	15·7	0·60	0·15
Birth	6·65	20·4	0·60	0·33

Stem cells seem to be present in the circulating embryonic blood at all the stages of gestation examined (Table 1). Larger absolute numbers and larger proportions of stem cells were seen in blood of 12 day foetuses than in 14–18 day foetuses. At birth, more colony forming units (CFU) per animal have been detected than at any other stage. To determine the comparative number of stem cells in a unit volume of injected blood, the number of CFU in 10^7 cells was calculated. It seems that, although there are more CFU per embryo at birth, there are probably fewer CFU per unit volume of blood than at 12 days gestation in C57BL/6J mice.

The possibility that peripheral cells or cell products in the injected blood induced formation of endogenous colonies in the lethally irradiated host[11] has also been investigated. Foetal C57BL/6J liver cells, 14 days gestation, which include CFU[10], were diluted to 10^6 cells per ml. either with 0·9 per cent saline or with noncomplicating peripheral blood cells from adult WBB6F_1-W/W^v mice (known to have only 1/200 of the normal ability to produce spleen colonies[12]) in saline. The same number of CFU was detected in hosts whether or not the diluent accompanying foetal liver implants contained W/W^v erythrocytes.

The demonstration of erythroid stem cells in embryonic and newborn mouse blood suggests that during development stem cells can use this pathway to migrate from one haemopoietic site to another. Our experiments have not eliminated the possibility that some stem cells may originate intrinsically in each haemopoietic organ. Also yolk sac stem cells may become incorporated directly into the developing foetal liver during embryonic rotation[2,3].

Evidence has been presented that the yolk sac contains stem cells[3] which are multipotential and can populate all known adult haemopoietic organs in the lethally irradiated mouse[13]. Stem cells originating in the yolk sac may, in fact, be the original source of all haemopoietic stem cell progeny in the organism[13]. It is interesting that in the present study higher proportions of circulating stem cells were seen at 12 days, when the liver may have been adding stem cells[10], than at 14–18 days, when liver haemopoiesis was at its maximum level[14].

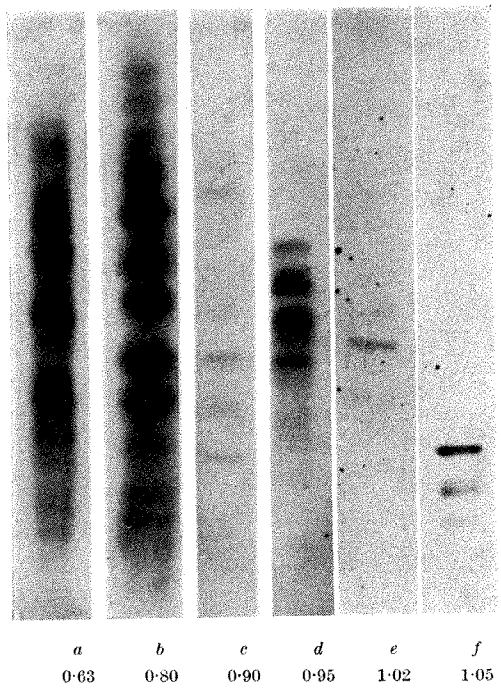

Fig. 2. Isoelectric spectra and heterogeneity indices of antibodies to DNP. Isoelectric focusing of sera was carried out using pH 5–8 ampholine carrier ampholytes in thin layer polyacrylamide gels[11], and anti-DNP components were visualized, after interaction with ^{131}I-DIHP-DNP-lysine, by autoradiography (A. R. W., in preparation). The details of immunizing regime and time of bleed for each rabbit were as follows: *a*, *c* and *d*, neonates primed with 0·1 mg, DNP_9-BGG with incomplete Freund's adjuvant; bleed taken 13, 9 and 5 days after boost 11; ages 54, 50 and 46 days respectively; *e*, a neonate primed with 0·1 mg DNP_9-BGG with incomplete Freund's adjuvant; bleed taken 8 days after boost 1; age 23 days: *b*, a rabbit primed with 1 mg DNP_9-BGG in saline on day 26; boosted with 2 mg DNP_9-BGG in saline on day 45; boosted with 2 mg DNP_9-BGG with complete Freund's adjuvant on day 97; bleed taken 10 days after boost 11; age 107 days: *f*, a murine anti-DNP antibody selected in CBA mice by cloning of antibody-forming cells[16]. The heterogeneity index was measured for each antiserum by a hapten-binding procedure[12]; each value represents the average of at least three determinations.

Molecular Restriction of Anti-hapten Antibody elicited in Neonatal Rabbits

THE origin of the diversity of antibody combining sites is one of the crucial questions of immunology. Many workers, hoping for evidence from structural studies of homogeneous antibodies, have attempted to elicit antibodies with restricted heterogeneity[1–6]. Another approach to the problem is to study the ontogeny of antibody diversity[7–10]. These and other approaches have been hindered by inadequate criteria for judging antibody heterogeneity. Techniques for the direct analysis of isoelectric heterogeneity of specific antibodies (A. R. W., in preparation) have facilitated the search for homogeneous antibodies and made it possible to study developmental aspects of diversity. These two approaches are combined in the studies we report here on the anti-hapten antibodies produced by neonatal rabbits. We have found that in the initial response to a heterogeneous presentation of hapten, neonatal rabbits frequently produce anti-hapten antibodies with restricted isoelectric spectra. The term "restricted" is used relative to the spectra of antibodies produced in adult animals. In certain neonates, the antibody spectrum resembled that characteristic of a single clone (monoclonal antibody).

New Zealand white rabbits were injected intramuscularly with DNP_9-BGG within 11 h of birth unless otherwise stated. The dose of antigen and the presentation (saline, incomplete or complete Freund's adjuvant) were varied. Animals were bled by heart puncture at 12 days. Subsequent subcutaneous injections of antigen in saline were followed by serial bleedings at 4–5 day intervals (Fig. 1). Aliquots (100 μl.) of each serum were analysed by isoelectric focusing in thin layer polyacrylamide gels[11] followed by detection of specific anti-DNP antibody components by the use of ^{131}I-α-N-(3,5-di-iodo-4-hydroxyphenacetyl)-ε-N-(2,4-dinitrophenyl)-L-lysine (^{131}I-DIHP-DNP-lysine) (A. R. W., in preparation).

A total of 42 rabbits has been examined so far and of these 81 per cent produced anti-DNP antibody either before or immediately after the second presentation of antigen. Antibodies with restricted isoelectric spectra (relative to adult antibodies) were found in 61·5 per cent of the responding neonates. 100 μg DNP_9-BGG in incomplete Freund's adjuvant most frequently elicited a restricted response. Typical isoelectric spectra are illustrated in Fig. 2; spectra were classed as heterogeneous (Figs. 2*a* and *b*), restricted (Figs. 2*c* and *d*) and mono-

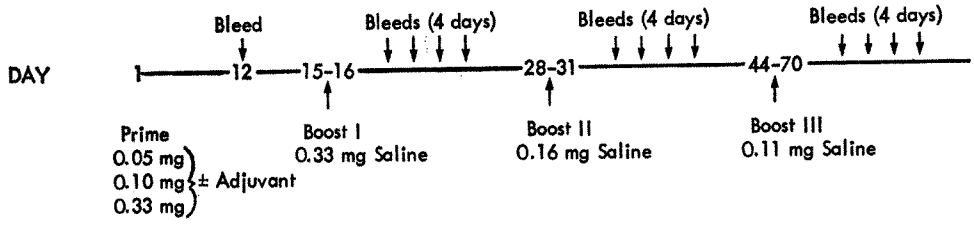

Fig. 1. Injection and bleeding schedule for neonatal rabbits. DNP_9-bovine γ-globulin (DNP_9-BGG) was injected intramuscularly in various amounts as shown, either as a solution in saline or emulsified with either complete or incomplete Freund's adjuvant. The age of the rabbit is given in days. Bleeds were taken at 4-day intervals after each boost injection of DNP_9-BGG.

clonal (Fig. 2*e*). The corresponding values of the heterogeneity index measured by the hapten binding procedure of Farr[12] are shown for comparison. The number of antibody bands seen in an isoelectric spectrum must be interpreted in terms of the multiple band patterns characteristic of monoclonal G-immunoglobulins; the spectrum of an IgG anti-DNP produced by a single antibody-forming cell-clone selected in CBA mice is shown in Fig. 2*f*. It has been shown for a G-myelom protein that the multiple band spectrum is a result of post-synthetic modifications of biosynthetically homogeneous protein (that is, the translation product of single mRNA sequences for light and heavy chains)[13]. There is an approximate correlation between the complexity of the isoelectric spectrum and the heterogeneity index of a given antiserum. This relationship does not necessarily hold in an exact way because the isoelectric spectrum yields both the number of different molecules and their proportional representation whereas the heterogeneity index is a complex function of these parameters with the spread of affinity constants.

The patterns of restriction observed in littermates have so far shown no interpretable similarities. Even from the small number of cases so far studied we can say that there is not a simple genetic control on the heterogeneity of antibodies produced early in life. From further study of littermates and litters from matings of the same parents (as well as back-cross) a pattern of control may emerge.

The persistent production of antibodies with the same simple isoelectric spectra by certain rabbits is of particular interest: it is important both from the standpoint of isolation of workable quantities of biosynthetically homogeneous antibody (the total antibody concentration in the sera of rabbits mounting a restricted response ranged from 50–250 μg/ml.) and in relation to the cellular control of antibody production. The course of immunization and the persistence of the restricted isoelectric spectrum of antibodies in one particular rabbit is shown in Fig. 3. The isoelectric spectra of antibodies after boosts 1 and 2 are strikingly similar. After boost 3 the spectrum shows a general resemblance to boost 2 antibody though there are several additional acidic lines. The heterogeneity index of hapten binding for boost 2 antibody (0·95) was consistent with the restricted isoelectric spectrum. But the heterogeneity index remained unchanged (0·95) for boost 3 antibody despite the more complex spectrum; this illustrates the extra sensitivity of isoelectric focusing as an assay for antibody heterogeneity.

The presence of similar antibody bands in each isoelectric spectrum (Fig. 3) indicates that antibody production by several individual clones has persisted up to 92 days during the injection schedule indicated. There is an increase in antibody levels after each boost so it is necessary to invoke recruitment of further specific precursor cells which upon antigenic stimulation yield clones of plasma cells continuing production of the particular molecular species of antibody. All rabbits studied eventually produced a heterogeneous antibody response to DNP-BGG, so precursor cells for clones producing other antibody species must be present or arise during the course of the experiment. The continued restriction on the heterogeneity of antibody production suggests a preferential generation of precursor cells for those clones originally proliferating. Production of antibody by the original clones may continue much longer than recorded here but our observations are limited by the onset of the heterogeneous response which would obscure the presence of the initially simple pattern.

Evidence from other sources has suggested that there may be long term continuity of similar antibody molecules. The continued production during a six-month immunization period of anti-*p*-azobenzoate antibodies with similar hapten binding properties has been deduced from light and heavy chain recombination studies[14].

Persistence of idiotypes over periods of up to 29 months has been reported by Oudin and Michel[15] though new idiotypes did arise during this period. An idiotype specificity does not, however, necessarily represent the product of a single clone.

The wide range of different restricted antibody patterns seen in litter mates must be viewed in the light of the significant number of heterogeneous responses in neonates. Taken together these two types of response support the notion that each neonate has extensive genetic potential for anti-DNP antibody production. This potential may be similar to that carried by adult rabbits which have invariably given a heterogeneous response to DNP-BGG

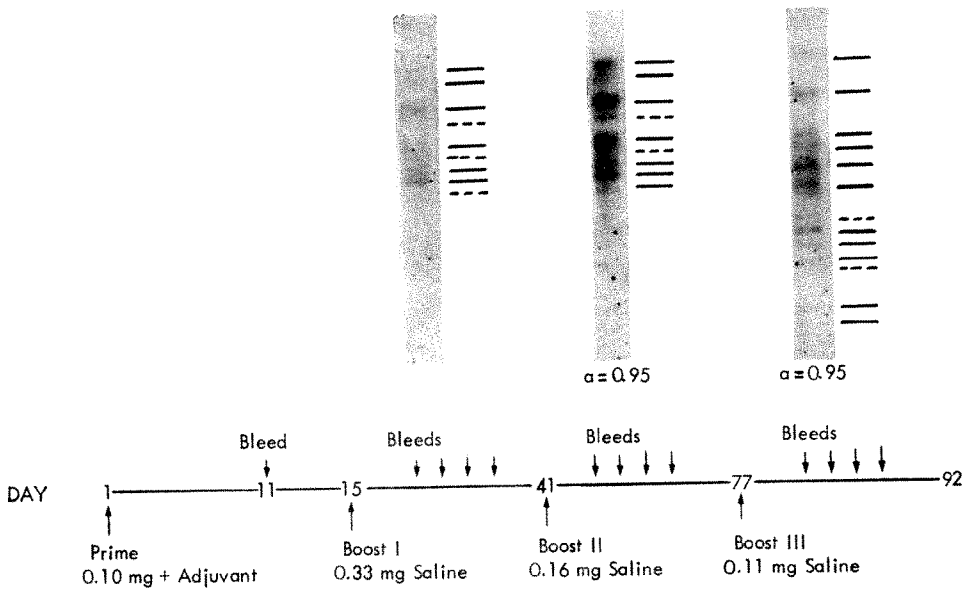

Fig. 3. The isoelectric spectra of anti-DNP antibodies produced in response to successive challenges with DNP_9-BGG. This neonatal rabbit was primed with 0·1 mg DNP_9-BGG and incomplete Freund's adjuvant and subsequently boosted with DNP_9-BGG in saline as indicated. Each serum sample was analysed by isoelectric focusing and antibodies to DNP-hapten visualized by autoradiography after development with ^{131}I-DIHP-DNP-lysine. The spectra and heterogeneity indices (*a*) shown refer to a single bleed in each case. Line drawings of each original autoradiograph spectrum are shown for clarity alongside the photographic reproductions.

even when production of antibody was low. Only 19 per cent of neonates did not respond to DNP-BGG presented a second time, though all surviving animals did eventually respond. It seems that individual neonates have differing capacities to express their extensive pre-existing genetic potential for antibody synthesis.

Specific *in vitro* Cytotoxicity of Thymus-derived Lymphocytes sensitized to Alloantigens

THE immune response to a specific antigen is characterized by the development of antibody-producing cells and of sensitized lymphocytes active in cell-mediated immunity. Although there is good evidence that antibody-producing cells are bone marrow-derived cells[1-2], the role of thymus-derived cells is less well understood. Development of cell-mediated immunity is impaired in neonatally thymectomized animals[3], and it is therefore likely that sensitized lymphocytes are thymus-derived cells. Spleen cell populations of mice immunized with allogeneic cells contain lymphocytes able to destroy *in vitro* appropriate target cells bearing the sensitizing alloantigens[4-5]. Earlier studies demonstrating the *in vitro* cytotoxic activity of sensitized thymus cells[6] suggested that cytotoxic cells found in immune spleen cell populations were thymus-derived. As shown recently[7-8] mouse thymus-derived cells in the peripheral lymphoid organs carry a surface marker, the θ alloantigen[9], and are lysed when incubated in the presence of anti-θ serum and complement. This study was undertaken to test the effect of anti-θ serum on the cytotoxic activity of spleen cells sensitized to alloantigens. Its effect on alloantibody-producing cells present in the same spleen cell populations was tested in parallel.

Anti-θ C_3H serum was prepared as follows: 3 month-old AKR/J mice received three intraperitoneal injections of 100×10^6 C_3H thymus cells at 3 week intervals. *Haemophilus pertussis* vaccine (1×10^9 organisms/mouse) was added to the thymus cells as adjuvant for the first immunization. The animals were bled 7 days after the last injection and their sera pooled. The specificity of the anti-θ C_3H serum was checked by indirect immunofluorescence using thymus cells from various strains of mice (AKR, C_3H, CBA, C57BL/6, Balb/C and DBA/2): thymus cells from all but AKR mice showed a strong fluorescent staining after treatment in suspension[10] with anti-θ C_3H serum and fluorescinated rabbit immunoglobulin G (IgG) antibody to mouse IgG. Another specificity test for the anti-θ C_3H was to check its absence of effect on haemolytic plaque-forming cells (PFC) present in spleens of mice immunized with sheep red blood cells (SRBC)[11-12]. C57BL/6 mice were injected with 4×10^8 SRBC intraperitoneally and killed 4 days later. Spleen cell aliquots were incubated with anti-θ C_3H serum, or various other antisera, and fresh rabbit serum as the source of complement. After incubation for 30 min at 37° C the cells were washed and tested for PFC according to the technique of Cunningham and Szenberg[13]. As indicated in Table 1, treatment of spleen cells with anti-θ C_3H and complement had no effect on PFC, while DBA/2 anti-C57BL/6 antiserum completely prevented the formation of PFC.

Table 1. PFC FROM SPLEENS OF IMMUNIZED C57BL/6 MICE REMAINING AFTER INCUBATION WITH AKR ANTI-θ C_3H SERUM AND COMPLEMENT*

Serum used for incubation†	No. of PFC per aliquot remaining after incubation with serum
Normal C57BL/6	352
C57BL/6 anti-DBA/2	358
DBA/2 anti-C57BL/6	0
Anti-θ	343

* Spleen cells were assayed 4 days after immunization with SRBC.
† 10×10^6 spleen cells in 1·8 ml. were incubated with 0·1 ml. of serum and 0·1 ml. of rabbit complement for 30 min at 37° C.

Previous studies have shown that lymphocytes sensitized to alloantigens could be detected *in vitro* by measuring their cytotoxic activity against ^{51}Cr-labelled target cells carrying the sensitizing alloantigens[4]. The effect of anti-θ antiserum was therefore tested *in vitro* on spleen cells sensitized by transfer into heavily X-irradiated allogeneic recipients[6]. Fifty million C57BL/6 spleen cells were injected intravenously into DBA/2 mice irradiated with 800 rad. Four days later, cell suspensions were prepared from recipient spleens. Spleen cell aliquots (20×10^6 cells) were mixed with AKR anti-θ C_3H serum (final dilution 1:10) and complement (fresh rabbit serum at a final dilution of 1:20) in a total volume of 2·0 ml. After incubation for 30 min at 37° C, the cells were washed and incubated with ^{51}Cr-labelled DBA/2 target cells (P-815-X2 mastocytoma cells)[14] at lymphoid cell–target cell ratios of 50:1 and 10:1. The radioactivity released from target cells was measured after 6 h incubation. The percentage of specific lysis was calculated after correction for ^{51}Cr release from target cells incubated with normal spleen cells. Sensitized spleen cells exposed to normal AKR serum and complement were used as controls. The results of two representative experiments are shown in Table 2. Pretreatment of sensitized spleens cells with anti-θ C_3H serum and complement completely abolished the cytotoxic activity. These results could not be ex-

† Based on cell counts performed before pretreatment of spleen cells.
‡ Target cells incubated with sensitized spleen cells for 6 h.

Table 3. EFFECT OF PRETREATMENT OF C57BL/6 IMMUNE SPLEEN CELLS WITH ANTI-θ C_3H SERUM AND COMPLEMENT ON *in vitro* CYTOTOXICITY AND ALLOANTIBODY PLAQUE FORMATION*

Serum used for pretreatment of immune spleen cells	Per cent specific lysis of ^{51}Cr-labelled target cells†	Antibody PFC per 10^6 immune spleen cells‡
Normal C57BL/6	74	70
Normal C57BL/6 + C	82	70
Anti-θ + C	0	72

* Cells obtained 5 days after transfer of 100×10^6 C57BL/6 spleen cells into heavily irradiated DBA/2 mice.

† DBA/2 target cells incubated in suspension with spleen cells for 6 h at a lymphoid cell-target cell ratio of 30 : 1.

‡ DBA/2 indicator cells incubated with spleen cells in 'agarose' for 1 h, complement added for another hour. Lymphoid cell–target cell ratio and PFC/10^6 spleen cells based on cell counts performed before pretreatment.

plained by simple reduction in spleen cell number. About 35 per cent of the spleen cells were killed by anti-θ serum and complement as tested by dye exclusion; at a lymphoid cell–target cell ratio of 50:1, however, anti-θ treated spleen cells failed to produce any significant activity, whereas control cells were still highly cytotoxic at a ratio of 10:1.

Similar experiments were performed using AKR and C_3H spleen cells sensitized to DBA/2 alloantigens. In this instance, pretreatment with anti-θ C_3H serum and complement had no effect on the cytotoxic activity of AKR sensitized spleen cells, whereas the activity of C_3H sensitized spleen cells was reduced by 80 per cent after such a treatment.

In another set of experiments, the effect of anti-θ serum was tested on immune spleen cells containing both sensitized lymphocytes and alloantibody PFC. Alloantibody PFC were detected with the help of a plaque assay system using as indicator cells the same target cells as employed in the cytotoxic assay system[6]. Immune spleen cells were obtained by transferring 100×10^6 C57BL/6 spleen cells into heavily irradiated DBA/2 mice. Five days later, recipient spleen cells were collected, treated with anti-θ serum and complement as indicated above and tested for the presence of sensitized lymphocytes and alloantibody PFC. Pretreatment with anti-θ serum completely abolished the cytotoxic activity, but had no effect on alloantibody PFC (Table 3).

These results clearly demonstrate that cytotoxic spleen cells, by contrast with PFC, carry the θ-alloantigen. Together with the results demonstrating *in vitro* cytotoxic activity of sensitized thymus cells[6], the data reported here indicate that *in vitro* target cell destruction by lymphocytes sensitized to alloantigens represents a specific activity of thymus-derived effector cells of cell-mediated immunity.

Use of Transient Optical Rotation for Biopolymer Characterization

THE optical activity of macromolecules has long been recognized as a valuable indicator of certain molecular properties. Studies were initially made of the optical rotation of macromolecular solutions, that is, their ability to rotate the plane of polarization of incident plane-polarized light, at a single wavelength. Measurements were later extended to a variety of wavelengths so as to observe the dispersion of the optical rotation with wavelength, that is, optical rotatory dispersion (ORD).

The optical activity of macromolecules arises from the "short range" atomic asymmetry within the monomeric units and the "gross" asymmetry associated with the overall macromolecular conformation[1,2]. Optical rotation measurements are therefore sensitive to the three-dimensional, relative atomic array of the macromolecule and reveal changes in structure with variation in environmental conditions; for example, the helix-to-coil transition of α-helical polypeptides[3,4], the unfolding of proteins to reveal subunit structures[5], the denaturation of proteins[6], and the aggregation of large molecules[7,8]. Yet the optical rotation method has a great deficiency which is not shared by most other experimental techniques: it provides no measure of the physical dimensions of the solute molecules; it does not distinguish between long and short helices of the same type because they have the same specific rotation.

There is much interest in experimental systems which indicate the physical properties of polymer molecules through relaxation effects. Dielectric dispersion[9], electric birefringence[10], fluorescence depolarization[11], electric field scattering[12], viscoelastic relaxation[13], nuclear magnetic resonance[14], and some flow birefringence experiments[15] fall into this category. Each provides a number of specific molecular parameters, and they have in common the evaluation of a relaxation time (τ). This parameter is especially useful because it can be readily related to the size and shape of the molecule. Another advantage is that the methods are often rapid.

We report here our initial success with a new experimental method which yields both the structural information obtained from ORD experiments and information on the molecular geometry from evaluation of the relaxation time τ. It has the additional potential ability to give such electrical parameters as the permanent and induced dipole moments of the molecules. The latter give further insight into the local molecular structure and form a link between this and the overall molecular size and shape. The procedure and calculation can be very rapid.

Molecular optical activity generally differs along specific axes of a molecule. Thus, the specific rotation associated with the major axis of a helical molecule differs from that of a transverse or minor axis. In solution, the molecules assume random orientations so that the solution itself exhibits no anisotropy in optical rotation. This is the case for conventional measurements with existing commercial polarimeters where some average rotation is recorded. If the solute molecules are partially or completely aligned using an electric, magnetic, acoustic or flow field, for example, the optical rotation changes as the direction of the light beam becomes predominantly associated with a particular axis of the solute molecules. The magnitude of the rotation change is related to the degree of molecular orientation which is a function of the particular molecular property causing the orientation. For electric fields, which form the subject of this work, the molecular dipole moments are responsible. Tinoco and Hammerle[16] have derived equations relating the change in the observed optical activity to the intensity of applied, continuous direct current electric fields. Tinoco[17] has subsequently studied the response of poly-γ-benzyl glutamate solutions to direct current fields of the

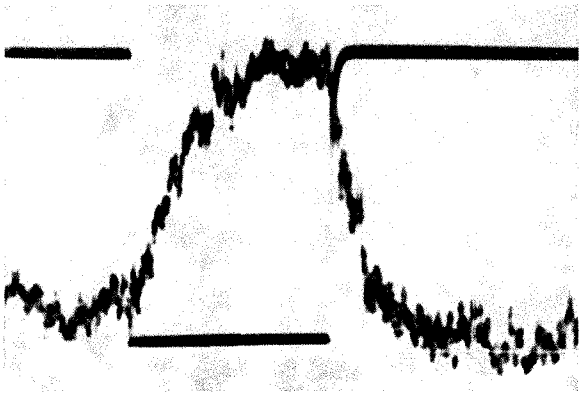

Fig. 1. Typical transient change in the optical rotation. Data for a 2 per cent solution of poly-benzyl glutamate in ethylene dichloride. $E = 1$ kV cm^{-1} and the pulse duration was 10 ms. An incident wavelength of 546 nm was used.

order of 4 kV cm^{-1}. Most of the interest in optical rotation concerns the study of biopolymers which are usually investigated in aqueous or conducting solvents. High voltage direct current fields have serious limitations because of electrophoresis, conductivity and heating effects. Further, the experiments do not enable calculation of molecular relaxation times. Improvements can be made by using alternating current fields or, better, short duration pulsed fields as reported here.

When the electric pulse is initiated the molecules become orientated and aligned but require a finite time to do so that depends on their size and shape. Once orientated, the system remains in this state, but when the field is removed, the molecules revert to a random distribution. The overall transient response in the optical rotation is thus an exponential build-up followed by an exponential decay. The build-up curve depends on two properties: the molecular geometry and the interaction of the applied field with the molecular permanent and induced dipole moments. The decay is, however, the result of brownian disorientation alone and depends only on the molecular geometry. By analogy with other electro-optic effects[18], the decay transient should obey the equation:

$$\Delta\theta = \Delta\theta_0 \exp(-2t/\tau) = \Delta\theta_0 \exp(-6Dt) \qquad (1)$$

where $\Delta\theta$ represents the change in the optical rotation from its residual (or zero field) value at any time t after the field is switched off. $\Delta\theta_0$ is the equilibrium of $\Delta\theta$ at $t = 0$. The rotary diffusion constant D is given by $D = 1/3\,\tau$.

Poly-γ-benzyl glutamate with a molecular weight of 300,000 was obtained from Koch-Light. It was dissolved in ethylene dichloride (a helix promoting solvent) to make a 2 per cent solution and was then filtered through a 5 μm 'Millipore' filter. A Bellingham and Stanley type 'Pepol 60' polarimeter was used to measure the optical rotation of the solution. Changes in the optical rotation can be observed if the field is applied either parallel or perpendicular to the direction of the light beam. Although the greatest effect is observed when the beam is perpendicular to the field[16,19], this condition also gives rise to induced birefringence which is difficult to separate from the optical rotation changes. Birefringence is not encouraged when the light is parallel to the field direction. This arrangement was therefore adopted in these measurements. Three basic modifications were made to the commercial apparatus. First, a special cell was constructed from a solid piece of polytetrafluorethylene. Conducting glass windows were spaced 1 cm apart, which enabled the field to be applied parallel to the light beam. Second, a rapid response and low noise photomultiplier with increased sensitivity was used. Third, a pulse generator was used to deliver pulsed fields of the order of 2 kV across the cell for durations of about 10 ms. The photomultiplier output was displayed on an oscilloscope and photographed. A xenon lamp and a suitable monochromator were used to produce the incident radiation of 546 nm. Full details of the apparatus and its mode of operation will be given elsewhere.

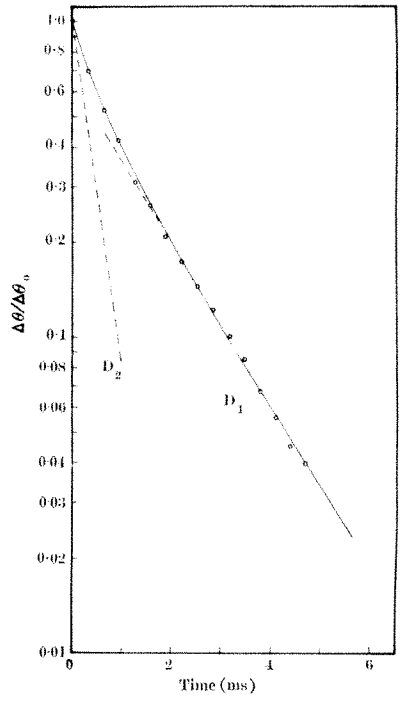

Fig. 2. Analysis of the transient decay. The natural logarithm of the ratio of the amplitude of the decay curve to its maximum value is plotted as the ordinate. The curve is a compound of two relaxation processes characterized by D_1 and D_2.

A typical pulse and transient response is shown in Fig. 1. Fig. 2 shows the analysis of the decay transient of Fig. 1 in terms of equation 1. The graph was not a straight line, indicating a spectrum of diffusion constants associated with the polydispersity of the solute. The transient optical rotation changes were therefore analysed on the basis of two average diffusion constants. The long-time data were fitted with a best line of slope $-6D_1$ to give D_1. The short-time data were then compensated for the contribution from D_1 to leave a second straight line of slope $-6D_2$. Rotary diffusion constants of 101 (± 8) s^{-1} and 400 (± 70) s^{-1} were indicated by this procedure. The analysis was checked using a rapid analogue simulator[20]. The length of the poly-γ-benzyl glutamate helices could be readily obtained from these values of D using Broersma's formula[21]. (The suitability of poly-γ-benzyl glutamate as a rod-like model for this study is discussed in ref. 22.)

To verify the transient optical rotation changes, transient electric birefringence measurements were made independently. The trace was similar to that of Fig. 1 except that it was much less noisy. It corresponded to a single relaxation process with $D = 95\ (\pm 7)$ s^{-1}, similar to the principal component of Fig. 2. It is thus possible that the optical rotation method is more sensitive to polydispersity.

The chief advantage of the transient optical rotation method is that molecular relaxation times can be obtained in addition to conventional optical rotatory dispersion data. Further, the magnitude of the changes when equilibrium has been attained ($\Delta\theta_0$ in equation 1) can be interpreted with Tinoco and Hammerle's equation[16]

to give molecular dipole moments (μ). The additional data (τ and μ) complement those from ORD measurements. Not only should one be able to predict the presence and sense of helical structures from measurements before the application of the electric field, but one should also be able to obtain the helix length from τ and discern a number of prospective helical structures per monomer length in terms of the dipole moment. Optical rotation is already one of the most sensitive indicators of molecular conformation changes. It functions arbitrarily in that the rotation itself is detached from any geometric molecular parameter. Determination of molecular relaxation times and dipole moments therefore should be especially valuable for "mapping" the arbitrary changes in optical activity in terms of specific physical parameters. The suspected molecular changes could be confirmed quantitatively, so providing further insight into the mechanisms and origins of these changes. This should also be true of the molecular aggregations reported from optical rotation studies. Knowledge of τ and the dipole moments should give a clear indication of the nature of the aggregate at various stages throughout its formation or disruption. More specifically, in the case of associating helices, side-by-side, head-to-tail and head-to-head associations should be easily differentiated. The degradation of proteins and their unfolding into subunits may be followed by using these parameters. Measurement of τ alone using the electric birefringence method enabled one of us[23] to demonstrate the unfolding of the subunit structure of bovine plasma albumin as the *p*H of the solvent was varied.

Fig. 3. Transient optical rotation trace using a laser source. Data as for Fig. 1 except that $E = 2$ kV cm^{-1}, and an incident wavelength of 633 nm was used.

Using 'Polaroid' film to record the oscilloscope display of the transient behaviour and the simulator[20] to analyse the exponential response, τ can be recorded within microseconds and evaluated within 1 min of applying the pulse to the solution. Such rapid recording and analysis should be valuable for the study of denaturation and aggregation kinetics. Even more attractive would be the possibility of following various reactions involving enzyme activity of proteins or coenzymes. Finally, the method is suitable whatever the molecular size, so long as the material is optically active. With smaller molecules, however, higher voltages are required for molecular orientation.

There are three apparent disadvantages of the method. First, the sensitivity is low compared with the electric birefringence method. Second, difficulties are encountered arising from strain in the cell windows because of the conducting coating. Third, the response is noisy (see Fig. 1), although it may be improved by using a laser as the light source. For the trace of Fig. 3 we used a System-Computors type G3 helium–neon gas laser of wavelength 633 nm, and a detecting photomultiplier which was not very sensitive to the red light. Although this wavelength is less favourable for optical rotation measurements, the transient is much better than that of Fig. 1. A laser operating at a lower wavelength together with a suitably matched detecting phototube should give a proportionately improved response.

Relevance of Feedback Inhibition applied to the Biosynthesis of Hexosamines

Negative feedback inhibition has been demonstrated in the biosynthesis of hexosamines, where the end product, UDP-N-acetylglucosamine, potently inhibits the first enzyme of the sequence, L-glutamine D-fructose-6-phosphate aminotransferase (glucosamine-6-phosphate synthetase, EC 2.6.1.16)[1,2]. But to test if UDP-N-acetylglucosamine does indeed function as a physiological controller of the enzyme, two characteristics must be known: the cellular levels of UDP-N-acetylglucosamine and the response of the enzyme to the postulated modifier.

Expressed on the basis of cell water, the concentration of UDP-N-acetylglucosamine in neonatal rat skin was determined by Hardingham and Phelps[3] as 0·22 mM and has been variously quoted for rat liver[4–8] as 0·3–0·8 mM, the mean value being 0·55 mM. This concentration has been reported to remain virtually constant for 8 h (ref. 4).

L-Glutamine D-fructose-6-phosphate aminotransferase was purified 400 times from rat liver and from the skins of 1 day postpartum rats by the procedure of Winterburn[9], so utilizing the protective action of the substrate, fructose 6-phosphate. The activity of the enzyme was measured by assaying for formation of glucosamine 6-phosphate by a modification of the Morgan–Elson method[10] after incubation at *p*H 7·5 and 37° C in the presence of non-limiting concentrations of the substrates[9]. Because some regulatory enzymes become desensitized to ligands during purification, the ligand response characteristics

(substrates and modifiers) of the glucosamine 6-phosphate synthetase were checked at each stage of the purification and found to be constant. The properties of the purified enzyme seemed to approximate to those observed *in vivo*.

Studies of the effect of UDP-N-acetylglucosamine on the activity of the enzyme revealed that besides being highly inhibitory (87 per cent at 0·4 mM) the rate of formation of glucosamine 6-phosphate was virtually independent of the concentration of inhibitor at levels greater than 0·3 mM. Varying the concentrations of UDP-N-acetylglucosamine and the substrates showed this inhibition to be non-competitive for fructose 6-phosphate and uncompetitive for glutamine (using the nomenclature of Cleland[11]), the K_i values being collectively about 40 μM. In the presence of UDP-N-acetylglucosamine, glutamine displayed substrate inhibition characteristics. Thus three attributes —(*a*) the highly inhibitory non-varying cellular concentration of UDP-N-acetylglucosamine, (*b*) the substrate inhibition by glutamine in the presence of UDP-N-acetylglucosamine and (*c*) the K_m for fructose 6-phosphate (0·11 mM) situated within the fluctuating cellular level of this metabolite (0·04–0·14 mM) (ref. 12) suggest that here feedback inhibition constitutes an inefficient and inflexible way of controlling a biosynthetic pathway.

Table 1. EFFECT OF AMP, GLUCOSE 6-PHOSPHATE AND UTP ON THE ACTIVITY OF THE ENZYME IN THE PRESENCE AND ABSENCE OF UDP-N-ACETYLGLUCOSAMINE

Additions	Activity (μmole/mg protein/h)	Activity in presence of 0·05 mM UDP-N-acetylglucosamine	Percentage inhibition
	Experiment 1		
None	0·86	0·61	29
+0·5 mM AMP	0·80	0·51	36
+2·0 mM AMP	0·75	0·40	47
+1·25 mM UTP	0·92	0·80	13
+2·5 mM UTP	0·89	0·86	3
	Experiment 2		
None	0·65	0·43	34
+0·25 mM glucose 6-phosphate	0·63	0·36	43
+1·0 mM glucose 6-phosphate	0·63	0·35	45

Each incubation contained: 50 mM Tris, 1 mM EDTA, 100 mM KCl, 3 mM fructose 6-phosphate, 6 mM glutamine adjusted to *p*H 7·5 in a final volume of 0·6 ml.; other additions were made as indicated. In experiment 1 each incubation contained 60 μg protein; in experiment 2, 70 μg. Incubations were for 1 h at 37° C.

A search for possible cellular metabolites which might affect the further regulation of this pathway revealed that physiologically significant levels of AMP, glucose 6-phosphate and UTP[3,12] modified the activity of the enzyme, but only in the presence of UDP-N-acetylglucosamine. As shown in Table 1, AMP and glucose 6-phosphate potentiated the inhibitory action of UDP-N-acetylglucosamine while UTP behaved as an activator. Further investigation showed that AMP (Fig. 1) acted by decreasing the apparent K_i for UDP-N-acetylglucosamine—leading to increased inhibition (glucose 6-phosphate behaved similarly to AMP); while UTP (Fig. 2) increased the apparent K_i—leading to a relief of inhibition. The effects evoked by AMP and glucose 6-phosphate were especially interesting because these metabolites have been implicated in the regulation of carbohydrate metabolism.

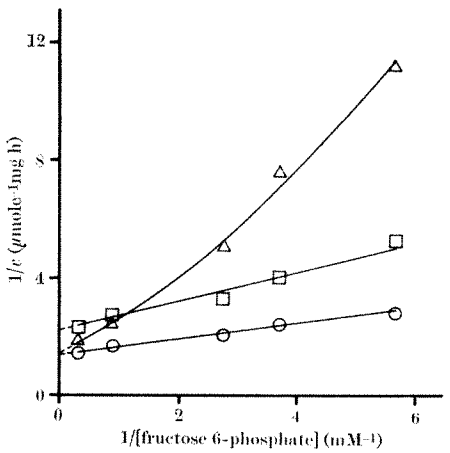

Fig. 1. Each 1 h incubation contained: 50 mM Tris, 1 mM EDTA, 100 mM KCl, 6 mM glutamine and 25 μg enzyme adjusted to *p*H 7·5 in a final volume of 0·6 ml. The additions were: ○, 1 mM AMP; □, 0·025 mM UDP-N-acetylglucosamine; △, 0·025 mM UDP-N-acetylglucosamine+1 mM AMP.

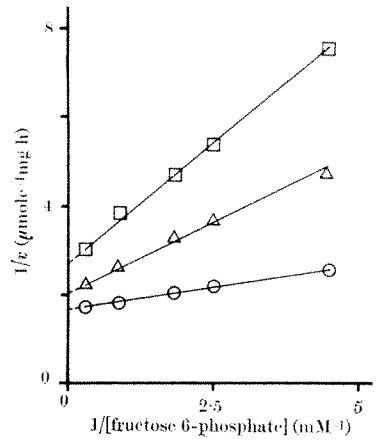

Fig. 2. Each 1 h incubation contained 50 mM Tris, 1 mM EDTA, 100 mM KCl, 6 mM glutamine and 40 μg enzyme adjusted to *p*H 7·5 in a final volume of 0·6 ml. The additions were: ○, 1·5 mM UTP; □, 0·05 mM UDP-N-acetylglucosamine; △, 0·05 mM UDP-N-acetylglucosamine + 1·5 mM UTP.

In the cell, therefore, assuming no marked compartmentation in the distribution of these effectors, the enzyme should be combined with its inhibitor giving rise to the prediction that in the intact cell the full potential activity will not be realized, and that the "normal" activity is that displayed by a heavily inhibited enzyme. Hardingham and Phelps[3] calculated that in neonatal rat skin the flux through the hexosamine pathway was 0·09 μmole/g wet weight/h. Careful extraction of glucosamine 6-phosphate synthetase from this tissue revealed that this enzyme has a potential maximal activity of 1·0 μmole/g wet weight/h (ref. 9). In rat liver, Spiro[13] found the hexosamine flux to be 0·1 μmole/g wet weight/h whereas the calculated maximal activity of the synthetase in this tissue is 2 μmole/g wet weight/h (ref. 9). In these different tissues, therefore, there was an order of magnitude discrepancy between the potential and realized rates, suggesting that the prediction regarding the heavily inhibited enzyme may be basically correct.

We propose that the primary control on the flux through the hexosamine pathway is at the level of the glucosamine 6-phosphate synthetase. This control is not by a fluctuation in the UDP-N-acetylglucosamine concentration but is through an alteration in its binding constant evoked by the other modifiers. A secondary control in this pathway by N-acetylglucosamine 6-phosphate inhibiting either the acetyltransferase or glucosamine 6-phosphate synthetase as suggested by Kent[14] is at present under investigation. Possibly UDP-N-acetylglucosamine should be regarded as an "antifactor" instead of its present classification as a feedback inhibitor.

This type of control mechanism, a straightforward extension of the present theories on the mode of action of modifiers, although here advanced for the case of hexosamine biosynthesis, may be far more prevalent in other metabolic pathways than at present envisaged.

Protein Degradation and Synthesis in Amino-acid Deficiencies

IT is well known that most body proteins are continually degraded and resynthesized. The protein content of various organs must represent the net balance between synthesis and degradation over some period of time. Nutritional or other factors which influence the protein content of tissues might act on either protein synthesis or degradation or both.

Most effort has been directed toward studies of the rates of protein synthesis using isotopically labelled amino-acids. The difficulties in interpreting such studies are well known[1–3]. These include the assumption that the amino-acids are uniformly distributed in an "amino-acid pool" (in fact, there are apparently multiple pools[4,5] which one may not be able to sample), and that a "steady state" exists. Many of the situations in which one wants to investigate the rates of protein synthesis or degradation are precisely those in which a "steady state" does not exist: for example, protein deficiency. But if amino-acids can be incorporated into proteins which are then broken down, and re-enter the "pool" to be reused, some of the usual assumptions seem doubtful, especially if this takes place on a local, perhaps even intracellular, basis.

In the technique devised by Goldberg[6–8] animals were injected with a labelled amino-acid and after the tissue proteins were labelled the animals were given an excess of the amino-acid by injection as well as a high protein diet. This technique would minimize the re-use of the labelled amino-acids and loss of label from the protein would then be a measure of protein degradation. Protein synthesis could be estimated from the total protein content of the tissue after correction for degradation.

We have used a similar technique to investigate the effects of specific amino-acid deficiencies on tissue protein degradation and synthesis. The studies were done with young adult female rats weighing approximately 200 g. They were fed a purified diet which contained a mixture of amino-acids as the sole source of protein. After one week on the diet they were injected with approximately 3·5 μCi of a ^{14}C labelled amino-acid and continued on the diet for an additional week. This allowed time for the tissue proteins to become labelled and for the activity of the amino-acid pool to fall to rather low levels. One group of animals was then killed for tissue analysis and the remaining animals fed the appropriate diets.

Data obtained from animals which had received a previous injection of L-^{14}C-lysine (New England Nuclear) and were then fed diets in which the lysine level varied from zero to 0·45 per cent over a six week period are shown in Table 1. The activity in the various tissues decreased with increasing levels of dietary lysine up to 0·3 per cent but the diet containing 0·45 per cent did not produce a further decrease. We interpret this to mean that levels of dietary lysine above 0·3 per cent are sufficient to dilute the lysine pool so that reincorporation of radiolysine is practically eliminated. A similar experiment done with animals injected with L-^{14}C valine and then fed several levels of valine produced similar results. A level of 0·22 per cent valine in the diet appeared to prevent reincorporation of labelled valine into the tissues.

Table 1. TISSUE RADIOACTIVITY

Tissue	Dietary levels of lysine 0	0·15	0·30	0·45
	Per cent			
Plasma, d.p.m./mg N	1,052	830	594	616
Muscle, d.p.m./mg N	997	818	547	565
Liver, d.p.m./mg N	852	679	484	443
Kidney, d.p.m./mg N	808	585	396	386
Small intestine, d.p.m./mg N	692	523	285	313

Radioactivity of various tissues from animals injected with L-^{14}C-lysine and then fed diets containing various amounts of lysine for 6 weeks.

Table 2. LIVER PROTEIN DEGRADATION AND SYNTHESIS

Dietary valine	Total liver nitrogen	Total liver counts	Difference Nitrogen	Difference Counts	Total degradation	Total synthesis
Per cent	mg	d.p.m. × 10^{-3}	mg	d.p.m. × 10^{-3}	mg N	mg N
Control, 0·07 (zero day)	224·0	109·3	—	—	—	—
0·00 (6 weeks)	171·0	20·8	−53·0 (24·0%)	−88·5 (80·0%)	181·5	128·0
0·07 (6 weeks)	200·0	21·6	−24·0 (10·7%)	−87·8 (80·0%)	179·9	155·8
0·15 (6 weeks)	231·0	23·0	+6·5 (2·9%)	−86·4 (79·0%)	177·0	183·6

Animals labelled with ^{14}C-lysine; 6 weeks on diet.

In the next experiment the animals were injected with labelled lysine as before and then fed a diet containing 0·45 per cent lysine but with either 0, 0·07 or 0·15 per cent valine. Data on the liver protein are shown in Table 2. In the animals killed at the beginning of the experiment (zero day) the average liver contained 224 mg of total nitrogen and 109,300 c.p.m. After six weeks on the experimental diets, approximately 88,000 c.p.m. had disappeared (80 per cent of the original counts) irrespective of the level of dietary valine. We therefore calculate that during this time approximately 80 per cent of the original liver protein or 180 mg of nitrogen had been degraded. The change in total liver protein, however, was substantially less and this difference is a measure of the total liver protein synthesis during the six week period. The total liver protein nitrogen synthesized is shown in the last column. The synthesis of new liver protein was decreased by the complete valine deficiency but was still substantial. At the highest level of dietary valine, which allowed some growth in the animals, synthesis slightly exceeded the total protein degradation.

A similar experiment was done in which the animals were injected with labelled valine and then fed the diet containing 0·22 per cent valine but with various levels of dietary lysine. The data from the two experiments on the rates of protein degradation were similar. We calculate a mean liver protein degradation in six weeks of $79·6 \pm 1·4$ per cent compared with $80·1 \pm 1·2$ per cent in the previous experiments. The total degradation of kidney protein in the two experiments was 72·2 per cent and 69·2 per cent and of the total plasma proteins (calculated from an assumed plasma volume of 4·1 per cent of the body weight) was 80·4 per cent and 71·5 per cent. In each tissue examined, there was no evidence that the rate of tissue protein degradation was influenced by the level of valine or lysine in the diet, whereas the rate of synthesis was directly related to the level of these amino-acids supplied.

We therefore conclude that deficiencies of either lysine or valine and presumably other essential amino-acids do not stimulate the breakdown of tissue proteins and that the changes in protein content that do occur are due to different rates of protein synthesis.

Changes in the Properties of Reconstituted Collagen brought about by Mechanical Treatment

GROSS has shown that the decreasing ability of a collagen gel to pass back into solution when the *p*H or the temperature is lowered represents an ageing effect in *in vitro* collagen gels[1]. These alterations in physical properties may be a result of the formation of covalent cross linkages between oxidized lysine residues in one tropocollagen molecule and free lysine ε-amino groups in adjacent ones[2]. We have shown that similar changes in physical properties and alterations in the enzyme susceptibility of the precipitated collagen are caused by the application of cyclical mechanical stress to the collagen during the period of precipitation.

Polymeric collagen was obtained from three year old bovine achilles tendon by exhaustive extraction with 5 M NaCl to remove all the soluble proteins[3] and prolonged incubation with crude α-amylase. After dispersion in acetic acid and reprecipitation with NaOH, a solution was prepared in 0·2 M acetic acid containing 75 mg protein/100 ml., measured by the method of Lowry *et al.*[4] using gelatine as standard. This material conformed to the standards of purity suggested by Grant and Jackson[5] by having less than 1 mole of hexosamine and 6 moles of hexose per ninety-four residues of hydroxyproline. This solution was slowly neutralized by exposure to an atmosphere of moist ammonia at 20° C for 16 h. The precipitated gel, consisting of fine fibrils up to 2 mm in length, was shaken with acetic acid to determine the reversibility of the "ageing" process. After shaking for 5 h with 5 ml. of 0·2 M acetic acid, 46·6 ± 8·4 per cent of the gel prepared from 0·2 ml. of the collagen solution redissolved. Other samples of precipitated collagen were subjected to cyclical alterations in mechanical stress. These were produced by a specially designed piece of apparatus in which the collagen is stretched by precipitation in a nylon mesh, the area of which is extended by 33·6 per cent every 8 min by a piston. Collagen (0·2 ml. of 0·075 per cent solution) was applied to the centre of the nylon; the piston was set in motion, and the vessel containing the piston and mesh was filled with a mixture of nitrogen and moist ammonia. The rate of passage of the ammonia was regulated so that precipitation of the collagen fibres, as indicated by the appearance of opacity in the liquid in the nylon mesh, appeared after 3 h. A similar amount of collagen solution supported on an unstretched mesh was exposed to the same alkaline atmosphere in the body of the vessel at the same time.

Sixteen hours after the initial application of the collagen solution, disks of fabric 2·5 cm in diameter were cut from the stretched and unstretched samples. In one series of experiments the two separate pieces of fabric with their entrained collagen precipitates were shaken for 5 h in 5 ml. of 0·2 M acetic acid. In the other series they were divided into two equal portions; one was incubated in 5 ml. 0·2 M sodium acetate buffer (*p*H 7·8) containing 0·01 M calcium chloride and 100 μg of *Clostridium* collagenase, and the other was incubated in 5 ml. 0·15 M borate buffer (*p*H 8·4) containing 100 μg pancreatic elastase[6]. Both preparations were incubated at 37° C for 3 h and, after filtration, the solubilized protein was measured with a biuret reagent[7].

In contrast to the unstretched sample, only 15·0 ± 2·3 per cent of the stretched precipitate redissolved in acetic acid, a difference which is significant at the $P = 0{\cdot}005$ level. A 34 per cent stretch decreased the collagenase susceptibility of the precipitated fibres (measured in arbitrary units) from 56 to 42, whereas the elastase susceptibility increased from 8 to 17, an increase of 112 per cent. This change in relative susceptibility is significant below the $P = 0{\cdot}01$ level. It therefore seems that mechanical stress has two effects on neutralized collagen fibre: the fibrous gel is rendered less extractable with acetic acid and the susceptibility to digestion by elastase is increased whilst that by collagenase is decreased.

Keech[8] demonstrated (by electron microscopy) that the appearance of collagen gels changes considerably when it is stirred vigorously shortly after precipitation. Even the less drastic treatment used here may also affect the physical state of collagen. A reduction in solubility might indicate that an increasing number of cross links are formed. This could be attributed to an alignment of the molecules that brings the reactive centres in adjacent peptide chains sufficiently close to one another for reaction to take place. On the other hand, the changes which are observed in the relative enzymic susceptibility seem to necessitate exactly the opposite situation, namely one of denaturation and disorientation: Hall *et al.*[9] and Banga and Balo[10] have demonstrated that denatured collagen is more susceptible to elastase than native collagen. This contradiction can be rationalized, however, if one assumes that the stretching alters the spatial relationships of carboxyl and hydroxyl groups in the collagen molecule in a fashion that renders them capable of attracting and binding elastase, similar to that which occurs in elastin[11].

Increased Recovery of Anaesthetized Hypothermic Rats induced by Intracarotid Infusion

WE have shown previously that if rats were cooled to cardiac arrest without assisted ventilation, held thus for 30 min, and rewarmed with artificial ventilation, only 9 per cent of them recovered[1,2]. This incidence could be increased to 45 per cent if their abdomens were pumped

before rewarming[3,4]. In these experiments, if the abdominal pumping had failed to restart the heart, spontaneous respiration did not subsequently recover. We now report new measures which further increased the incidence both of the hearts restarting and the recovery of spontaneous respiration.

Thirty rats were anaesthetized without assisted ventilation, cooled until their hearts stopped, and left cooled in cardiac arrest for 30 min; their hearts were then excised and perfused with Eagle's solution on a Langendorff apparatus at 37° C. All resumed beating. A further series of seven rats were similarly cooled to cardiac arrest, and rewarmed for 15 min with artificial ventilation. When it was seen that their hearts had failed to restart, they were excised, and six of them restarted on perfusion. It was therefore concluded that during cooling changes in the chemistry of the coronary arterial blood occurred, which prevented the hearts from restarting, but that the cardiac muscle still had the potential to contract. Thus if the coronary arterial blood could be replaced *in vivo*, more rats might recover.

Centripetal injection of 2 ml. of dilute methylene blue in isotonic saline into the right jugular veins or right carotid arteries of each of six rats demonstrated that the coronary arteries were perfused by the latter route only. Two ml. of Eagle's solution were therefore injected intra-arterially in thirty-one cooled rats; twenty-six of them (84 per cent) restarted spontaneous respiration after abdominal pumping, and rewarming with artificial ventilation. In similar conditions, isotonic saline injected into the carotid arteries of seventy-one rats caused fifty-six of them (79 per cent) to respire. In both cases, the incidence of recovery was significantly greater than with abdominal pumping alone ($P < 0.001$). But injection of saline into the jugular veins of thirty-six rats followed by abdominal pumping caused eighteen of them (50 per cent) to recover, which was not significantly different from the incidence of recovery after abdominal pumping alone.

Thus whereas in previous experiments only 9 per cent of the cooled unventilated rats recovered spontaneous respiration on rewarming, the further measures of centripetal intracarotid injection of Eagle's solution or isotonic saline, as well as abdominal pumping, enabled 79 per cent to 84 per cent to recover. These findings may be relevant to resuscitation after cardiac arrest in man.

Mechanism of Toxicity of Injected CS Gas

IN 1928 Corson and Stoughton[1] prepared a number of benzylidene malononitriles, including 2-chlorobenzylidene malononitrile (CS). Although these authors were primarily concerned with the isolation and chemistry of the condensation products of malononitrile and various aldehydes, sternutatory and irritant properties on the part of some of the compounds were reported. CS is now the active material in a wide range of devices used against civil disturbances and in war (see, for example, refs. 2–6). Benzylidene malononitriles are reactive substances, and have been shown to form adducts with amines[7–10], *n*-butanethiol[10–12], Grignard reagents[13,14], hydrazoic acid[15], hydrogen cyanide[1,15–17], salts of certain transition elements[18,19], and trialkylphosphines[20–22]. Reactions also occur with hypochlorite[23–24], water[1,9,17,25,26], oxidizing[1] and reducing[7,27,28] agents. Certain aspects of the physiological effects[2,7,8,29–32] and toxic properties[23,33–38] of CS have also been studied. We here describe a brief investigation into the mechanism of toxicity of CS. Because elevated levels of thiocyanate have been found in the blood of human patients treated with 4-nitrobenzylidene malononitrile[39], and because malononitrile is one of the products when CS is hydrolysed in aqueous ethanol[9], the toxicities of cyanide and malononitrile have also received attention.

Various benzylidine malononitriles, including CS, were synthesized by way of the base-catalysed condensation of malononitrile with the appropriate aldehyde[1]. CS itself was administered exclusively in solution in arachis oil (5–20 mg/ml.); other derivatives were given in either oil (0·19 mmoles/kg body weight) or dimethyl sulphoxide. Aqueous solutions of malononitrile (4–10 mg/ml.), potassium cyanide (0·5 mg CN/ml.) and sodium thiosulphate (50 mg pentahydrate/ml.) were prepared just before use. The compounds were administered to adult male or female mice (LAC strain) by intraperitoneal injection.

LD_{50} values were derived graphically[40,41] (Table 1). The figure for malononitrile is in good agreement with the previously reported value of $12{\cdot}75 \pm 0{\cdot}39$ mg/kg[42], by the same route of administration. Both the symptoms and the onset of poisoning by CS and malononitrile were very similar at dosages of comparable molarity. Different degrees of intoxication were noticed within 5–15 min of the injection of sublethal amounts of either compound, depending on the dose. The animals panted vigorously, and were soon gasping for breath. When lethal amounts were injected, the manifestations were more severe, and culminated in a loss of consciousness. The onset of panting and gasping was more rapid, but both phases could still be clearly distinguished. The rate of gasping decreased until death ensued, generally 15–60 min after injection. Convulsions were observed in a minority of animals.

Symptoms of cyanide poisoning showed some similarities with those of CS and malononitrile, provided that the dose did not exceed 4–4·5 mg/kg; above these levels death occurred rapidly. At dosages of 2·5–3·5 mg/kg the animals collapsed within 1–2 min of injection, and were briefly convulsed. Although the panting phase was difficult to discern, gasping was readily apparent. In those animals which recovered, the rate of gasping gradually increased; a phase of violent shivering very often set in, which persisted for up to 10 min. Animals which failed to recover usually died within 6–25 min of injection.

Table 1. TOXICITIES OF CS, MALONONITRILE AND CYANIDE

Agent	LD_{50} ± standard error, mg/kg body wt.	LD_{50} ± standard error, mmoles/kg	Number of animals used
CS	35 ±1·2	0·186 ± 0·006	70
Malononitrile	12·9 ± 0·6	0·196 ± 0·009	72
Cyanide (as CN)	3·0 ± 0·09	0·115 ± 0·004	70
2-Chloro-β-cyanocinnamamide*	120 ±7·4	0·58 ±0·036	57

* Given as a solution in dimethyl sulphoxide. Vehicle dose never exceeded 6 ml./kg.

The toxicity of malononitrile has been ascribed to a gradual conversion to cyanide in the tissues[43,44]. The closeness of the LD_{50} values for malononitrile and CS when expressed on a molar basis (Table 1) therefore suggested that the poisonous effect of CS might also be caused by the liberation of cyanide. This possibility was tested by injecting sodium thiosulphate[42–45] (0·3 ml.) within 6–8 min of administering up to five times the LD_{50} of malononitrile or CS. Recovery was rapid in the case of malononitrile; gasping soon gave way to hyperventilation, which was sometimes accompanied by shivering and mild tetany,

The animals began to walk within 5 min of receiving thiosulphate, and survived without any permanent ill-effects. In the short term thiosulphate produced identical results in mice which had received CS, but the animals began to die 20 h after injection. Most deaths were recorded within the first 48 h, but survivals of up to 5 days were observed. Treatment with thiosulphate enabled about half the animals to survive 70–140 mg/kg of CS, but only one mouse out of a total of ten survived a dosage of 175 mg/kg. Moribund animals often exhibited a degree of hypothermia which was readily apparent to the touch (compare ref. 43).

Post-mortem examinations were performed on animals within a few minutes of death following the administration of CS, with or without thiosulphate. Macroscopically, the internal organs showed no abnormality apart from congestion, which was especially apparent when survival had been prolonged with thiosulphate. Histological examination of sections of liver, kidney, adrenals, spleen, heart, lung, and brain stained with haematoxylin and eosin from fifteen animals revealed no differences between creatures dying within 90 min of CS administration and four mice which were killed 1 h after injection of vehicle alone. At the microscopical level there appeared to be no noteworthy changes, other than venous congestion, in the organs of animals whose survival had been prolonged by the administration of thiosulphate. Neither necrosis nor significant cellular degeneration was observed in test or control mice.

Other benzylidene malononitriles were tested on mice to see if toxic effects were produced, and whether or not these were reversible by thiosulphate. In the short term benzylidene malononitrile itself produced symptoms precisely similar to those caused by CS; at the LD_{50} for CS (0·19 mmole/kg body weight) five animals died out of a total of eight. At three times this level (0·57 mmole/kg) all five animals in another group died. Five others which received thiosulphate, however, made rapid and permanent recoveries. On the other hand, 4-hydroxybenzylidene malononitrile (0·19 mmole/kg) induced panting but not gasping in four animals without causing fatalities; twice this dose killed two animals out of four. At a higher level still (0·57 mmole/kg) there were no survivors from two groups totalling ten animals. The effect was insensitive to thiosulphate, regardless of the order of administration. Deaths occurred within minutes of injection, and the corpses went into rigor. When 3-nitrobenzylidene malononitrile (0·19 and 0·57 mmole/kg) was injected into ten animals, all died, mostly between 6 and 22 h of injection. Gasping was observed in most cases; at the higher dose level thiosulphate exerted no remedial action. In a further group of six animals, 4-nitrobenzylidene malononitrile (0·57 mmole/kg) produced negligible effects in the short term, but four animals died 2–6 days following administration. The action was again insensitive to thiosulphate. Dimethyl sulphoxide was employed as vehicle at a level of 3·5 ml./kg for doses in excess of 0·19 mmole/kg.

Patai and Rappoport[9] have implicated 1-(2-chlorophenyl)-1′-hydroxy-2,2′-dicyanoethane as an intermediate in the hydrolysis of CS to malononitrile and 2-chlorobenzaldehyde. Since the same mechanism of breakdown might operate to some extent in living tissues, an attempt was made (G. R. N. J., Zauli, C., and Diamond, P. S., in preparation) to prepare this compound as Horner and Klüpfel[20] prepared 1-phenyl-1′-hydroxy-2,2′-dicyanoethane from benzylidene malononitrile. The actual product obtained, however, seemed to be 2-chloro-β-cyanocinnamamide (G. R. N. J., Zauli, C., and Diamond, P. S., in preparation). This material, although toxic, was not only much less poisonous than CS (Table 1), but also produced quite different symptoms, rendering the animals inert but not unconscious. A small number of mice died within a few hours of injection; most deaths occurred 20–40 h later. Only one animal, given 160 mg/kg, encountered the respiratory difficulties described above, and died 10 min after injection.

The effect of benzylidene malononitriles on the body is seen to depend critically both on the nature and on the position of substituents in the aromatic nucleus. The general effects of 4-hydroxybenzylidene malononitrile and the insensitivity to thiosulphate of its lethal action are not at variance with its ability to uncouple oxidative phosphorylation[46]. CS, however, has two distinct loci of toxicity, of short-term and long-term duration. The short-term locus, which is the more toxic of the two and which is also exhibited by benzylidene malononitrile, is akin to the action of malononitrile. This effect involves the liberation of cyanide within the body, and is reversed by thiosulphate. The resemblance of the symptoms to those produced by malononitrile and benzylidene malononitrile suggests that rates of cyanide formation from the three compounds are similar, and underlines the view that benzylidene malononitriles are reactive compounds. In order to explain its sternutatory properties, Holmes[7,8] has suggested a multistep scheme for the breakdown of CS. A convincing explanation of the whole range of effects must take differential racial sensitivity[31] into account. According to this hypothesis, CS could react with strongly basic amino groups, such as found in lysine residues, to give benzylamine adducts. These would undergo biologically catalysed oxidation to give imines or their tautomers before breaking down to form the $—CH(CN)_2$ ion and 2-chlorobenzoylamino derivatives. The carbanion would then be rapidly protonated to give malononitrile[47]. A further possibility is that decomposition might occur in the same way as in aqueous ethanol[9], but despite the stoicheiometric molar basis of toxicity on the part of CS, malononitrile (Table 1) and benzylidene malononitrile, the slowness of CS hydrolysis[9] and the similarity between the rates of poisoning of the three compounds suggest that cyanide ions may be cleaved from the original benzylidene derivatives at least to some extent without intermediate breakdown to malononitrile and the corresponding aldehyde.

Unlike benzylidene malononitrile and malononitrile itself, CS exhibits a long-term locus of toxicity, the mechanism of which has not been elucidated. Among the factors which actually cause death might be included general irritation[29], shock, or stress, although damage to the adrenals was not observed in the present work (see ref. 35). Comparisons with or extrapolations to the effects of CS aerosols on people are extremely difficult to make, but accidental ingestion of the material might cause poisoning in a way similar to malononitrile[48]. One immediate point of difference concerns the cytotoxic effect of CS in the respiratory tract of animals, where solid particles produced necrosis at sites of impact[35]. This necrosis may be a direct consequence of high local concentrations of the material or of its breakdown products, a situation which does not obtain in the present work.

We thank Professor C. Long and Professor J. L. Turk for their kind interest. This study was carried out during tenure (by G. R. N. J.) of the Lilian May Coleman Fellowship for Cancer Research.

Mechanism and Prevention of Inert Gas Narcosis and Anaesthesia

BECAUSE of the raised partial pressure of nitrogen, compressed air induces symptoms of narcosis similar to those of the volatile anaesthetics[1,2]. Inert gases of the noble gas series, except possibly helium and neon[3,4], also cause narcosis and anaesthesia. Many mechanisms have been suggested for this narcosis[1,2,5–10] but those involving polarizability and molecular size seem most probable.

The Meyer–Overton theory infers preferential adsorption of the inert gas to the lipid constituent of cells, whereas alternatives involve the aqueous phase with the formation of clathrates[8] or ordered water[9] known as "icebergs". The use of fluorinated compounds, however, has provided evidence for the superiority of the correlation of anaesthetic potency to lipid solubility[11,12].

Most of the previously suggested mechanisms affecting membranes suggest an ion block as the cause of the narcosis[6,13,14]. The Meyer–Overton hypothesis would predict, on the contrary, an increased cation permeability through lipid membranes compared with the less likely hydrate theories, which predict decreased mobility[15].

In support of an increased permeability theory, Clements and Wilson[16] noted: "Inert gases, sufficient to bring about a standard effect in a biological system, act on a lipoprotein–water interface to produce a standard decrease of 0·39 dyne/cm in the interfacial tension". This results in expansion of the membrane and affects the dielectric constant at the interface. Their work supported lipid involvement and also implied the possibility of permeability changes. Later, Bangham *et al.*[17] reported that such changes in interfacial tension by volatile anaesthetics do increase ion permeability and concluded that "narcosis represents a transient reversible increase in membrane permeability to cations, higher concentrations resulting in a degree of permeability which the energy driven pumps in biological membranes cannot keep up with".

More recently, Bennett *et al.*[3] showed that increased pressures of nitrogen and argon, and also oxygen and carbon dioxide, similarly will adsorb to lipid membranes and affect the interfacial tension in accordance with the rule of Clements and Wilson[16]. Helium did not penetrate the membrane, even at 100 absolute atmospheres, showing that it is probably not narcotic. It is significant that no narcosis was detected in two men exposed recently to over 46 absolute atmospheres helium[4].

That such adsorption of inert gases to lipid membranes does cause an increase in intracellular ions is supported by *in vivo* studies showing a decrease of Na^+ and Cl^- in the cerebral spinal fluid of cats exposed to increased pressures of nitrogen and argon but not helium[18]; a decrease in plasma Na^+ and increase in erythrocyte Na^+ in men at 7 absolute atmospheres compressed air[19] and retention of urinary Na^+ and Ca^+ in divers exposed to 5·5 to 10 absolute atmospheres compressed air but not helium[20]. Similar electrolyte changes have also been reported during general anaesthesia and alcoholic intoxication[21,22].

In contrast, Halsey, Smith and Wood[23] found no *in vitro* evidence of an effect on active cation transport by ether or chloroform in erythrocytes until a concentration was reached which disrupted the membrane. At low concentrations, however, some evidence of increased cation transport was observed. Because the inert gases are only comparatively weak narcotics an effect on cation permeability seems more likely. Further, Mikikits *et al.*[24] have reported a general lack of correlation between inhibition of neuronal activity and red cell stabilization.

It is relevant also to consider the manner of the adsorption responsible for any resulting change in permeability. Benson and King[25] have postulated that this could well be electrostatic, involving preferential adsorption at charged sites on nerve cell membranes.

Some simple long-chain cationic detergents prevent liver necrosis in the rat resulting from carbon tetrachloride poisoning by preventing the associated intracellular accumulation of water, NaCl and calcium and loss of potassium and cellular proteins[26]. Such compounds are believed to be surface active and form complexes with lipids at lipid–water interfaces, especially if the former are negatively charged[27,28]. Anionic detergents, however, prevent neither such permeability changes nor liver necrosis. The results of these drug studies suggest that stabilization of the lipid membrane is achieved by the presence of either non-polar portions of amphipathic molecules (that is, with a hydrophobic portion and a polar group), or by the strategic positioning of positively charged groups at the water–lipid interface of the cell membrane.

If, as suggested here, the mechanism of inert gas narcosis is a preferential electrostatic adsorption to charged sites on neurone lipid membranes causing an increased ion permeability, cationic detergents should also prevent such narcosis. Experiments were therefore performed to

Table 1. EFFECT OF SURFACE ACTIVE ANIONIC OR CATIONIC DRUGS ON INERT GAS NARCOSIS IN RATS AT 0·9 O_2/6·41 N_2 ABSOLUTE ATMOSPHERE

study the effects of cationic and anionic detergents on inert gas narcosis in rats. In addition, because low concentrations of non-steroidal anti-inflammatory drugs protect erythrocytes against lysis, acetylsalicylic acid also was investigated. Earlier studies have established that aspirin, among a number of other drugs, does ameliorate narcosis in the rat[29,30].

Seventy male Wistar rats were used in the present investigation. The narcotic effect of exposure to a pressure of 0·9 O_2/6·41 N_2 absolute atmospheres for 45 min was obtained by measurement of the mean spike height of the a_2 (25–45 ms) − b_2 (15–60 ms) wave of five averaged cortical potentials, recorded from two scalp electrodes and an earth electrode on the tail and evoked by flash stimuli presented through a 1 inch window in the pressure chamber situated immediately in front of the face of the rat. A flash was presented every 1·5 s with a sweep time of 320 ms and the effect of 64 flashes averaged. Comparison of results at atmospheric pressure with measurements at pressure were expressed as the mean percentage change in evoked response[31]. The drugs were administered intraperitoneally 30 min before compression.

The results (Table 1) indicate that the anionic compounds had no significant effect on the 29·8 per cent mean reduction of the evoked response as a result of the raised nitrogen partial pressure. Thus narcosis was still present. The cationic drugs and acetylsalicylic acid were, however, significantly effective ($P<0·001$) in preventing the decrease in evoked response. These compounds are therefore acting in a manner similar to that with carbon tetrachloride poisoning[26]. The relationship of this action to permeability changes, such as the leakage of β-glucuronidase into the sera (Table 1), indicate that protection in the liver and probably also in the present study in the brain is attained by restoration of the cell membrane to normality with a consequent reduction in the mobility of ions across the membrane.

This accords with a mechanism of narcosis and anaesthesia involving electrostatic adsorption to the lipids of neurone membranes which causes increased permeability to ions and their redistribution between the intracellular–extracellular fluids in accordance with their concentration gradients. Such changes in ion distribution interfere with the ion movements necessary for propagation of potentials and failure of transmission at the synapse occurs involving a maintained depolarization.

Mauve Factor re-identified as 2,4-Dimethyl-3-ethylpyrrole and its Sedative Effect on the CNS

Irvine[1] and Hoffer and Mahon[2] reported on the occurrence of a compound giving a characteristic mauve colour with Ehrlich's reagent on paper. The significance of this metabolite is that it occurs with greater frequency in psychotic individuals. This finding has been confirmed by several investigators[3–5]. Ellman *et al.*[6], however, reported that a metabolite apparently identical to the one in question may be derived from phenothiazines and occurs in the urine of patients on phenothiazine therapy. Recently, Irvine[7] has identified the mauve factor as 2,4-dimethyl-3-ethylpyrrole on the basis of chromatographic and mass spectral studies. This report is concerned with the identity of the mauve factor, a critique of various isolation procedures used by different investigators and its pharmacological action on the central

nervous system (CNS). The possible CNS effect is important because several laboratories have postulated a metabolic product in the schizophrenic which may be stimulant and hallucinogenic.

The mauve factor fractionations were carried out by the charcoal adsorption procedure of Irvine[1] as modified by Sohler[3], the ether extraction procedure of Hoffer and Mahon[2] and the chloroform extraction procedure of Ellman *et al.*[6]. Urines were tested for the presence of phenothiazine derivatives by the ferric chloride procedure of Forrest *et al.*[8]. 2,4-Dimethyl-3-ethylpyrrole was obtained from Aldrich Chemical Company. In experimental procedure, the trained test rabbits, chronically implanted with skull electrodes, were unrestrained and unanaesthetized, prepared with indwelling ear vein catheters for remote drug injection, and mildly sedated with sodium pentobarbital (3 mg/kg, intravenously) to provide a controlled baseline level of reference. Six rabbits were used at each dose level. 2,4-Dimethyl-3-ethylpyrrole (in 'Tween', methyl-cellulose suspension) was administered at dose levels of 1, 5, 10 and 20 mg/kg. Cortical electrical activity, as reflected in the electroencephalogram (EEG), was evaluated using a technique of quantitative EEG amplitude analysis[9]. We confirmed that the chloroform extraction procedure described by Ellman does extract from urine of patients on phenothiazines a phenothiazine derivative having the same R_f in the isopropanol–ammonia–water system as bufotenine and the mauve factor. The compound is not found, however, in fractions prepared by the charcoal procedure of Irvine. Several patients on phenothiazines were run using both procedures. With the chloroform procedure these patients would have been found to be mauve positive. By the charcoal procedure they were negative (Table 1).

The first six patients were on therapeutic doses of phenothiazines. Of this group, five of the six were positive using Ellman's procedure, while five of the six were negative using Irvine's procedure. Also in this table are two patients who are not on any medication but who are mauve positive with all three procedures. Of the patients on phenothiazine, four of the six are positive using the Hoffer and Mahon ether extraction procedure. These four are also positive by Ellman's procedure, indicating that with the ether extraction procedure, phenothiazine derivatives would be detected and reported erroneously as the mauve factor. The results obtained with the various extraction procedures indicate that the isolation procedure used must have a high degree of specificity, for phenothiazine derivatives and even bufotenin reported in the urine of some schizophrenic patients have similar chromatographic properties to the mauve factor in the principal solvent systems used. The mauve factor seems to differ significantly from the phenothiazine derivative in that the colour produced with Ehrlich's reagent fades on standing while this colour only appears on heating in the case of the mauve factor. With Ehrlich's reagent, the phenothiazine derivative produces a fairly stable colour almost immediately. The phenothiazine derivative, unlike the mauve factor, reacts strongly with Dragendorf's reagent. Although these tests are not absolute proof of a difference because the differences in the concentration of reactants could account for the negative tests, it is highly probable that the mauve factor found by Irvine's procedure is not a phenothiazine derivative.

The identification of the mauve factor with 2,4-dimethyl-3-ethylpyrrole and related compounds by Irvine has been confirmed in this laboratory on the basis of paper and thin-layer chromatography. Table 2 presents the results of these studies with regard to mauve factor isolated from urine and synthetic 2,4-dimethyl-3-ethylpyrrole. This not only has identical chromatographic behaviour, but reacts typically with Ehrlich's reagent, giving a mauve spot which appears slowly on heating and (at the concentrations usually examined in urine) fades after a short time. Mauve factor samples isolated from urine by the charcoal procedure require further purification by thin-layer chromatography before satisfactory comparisons can be made by paper chromatography in the 20 per cent KCl and 8 per cent NaCl systems. The fractions obtained in the charcoal procedure were chromatographed as a streak on Mallinckrodt, silica gel G, in ethyl acetate–isopropanol–ammonia (9 : 7 : 4). The band corresponding to the mauve factor was cut out, eluted with methanol, concentrated *in vacuo* and spotted on paper. This material was also examined spectrophotometrically and reacted with Ehrlich's reagent and the product examined spectrophotometrically. In all cases the behaviour of the mauve fraction from urine was identical with that of 2,4-dimethyl-3-ethylpyrrole. Recoveries using the charcoal procedure are very good, of the order of 90–100 per cent, and this with studies of the intensity of the Ehrlich reaction indicates that in mauve positive subjects the daily urinary excretion of 2,4-dimethyl-3-ethylpyrrole would be of 0·2–1 mg/24 h.

Table 2. CHROMATOGRAPHIC BEHAVIOUR OF MAUVE FACTOR FROM URINE AND 2,4-DIMETHYL-3-ETHYLPYRROLE

System	Urinary mauve factor	R_f 2,4-dimethyl-3-ethylpyrrole	Bufotenine
TLC, silica gel, butanol–methanol (50 : 50)	0·86, 0·98	0·86, 0·94	0

which is easily oxidized. As well as the spot represented by 2,4-dimethyl-3-ethylpyrrole several faster moving related components are often observed. These have also been observed in mauve positive urines.

The association of the mauve factor with psychotic states has led to a testing of 2,4-dimethyl-3-ethylpyrrole for CNS stimulatory activity in rabbits. In brief, the CNS response to the mauve factor compound was essentially a progressive increase in the baseline sedation in proportion to increasing dose. Judging from this sedative effect the mauve factor can be eliminated as one of the possible stimulant metabolites producing over-arousal in the schizophrenic patient.

Triosephosphate Isomerase Gene not Localized on the Short Arm of Chromosome 5 in Man

THE assignment of the gene for triosephosphate isomerase (TPI, EC 5.3.1.1) on the short arm of chromosome 5 (ref. 1) needs confirmation. Sparkes *et al.*[1] reported diminished activities of TPI in the heterozygous range in a patient with a partial deletion of the short arm of chromosome 5 (cat cry syndrome). Both her parents, however, had normal values of this enzyme and were considered homozygous normal for the TPI gene. The authors concluded that the patient may have been hemizygous for TPI owing to loss of one TPI locus with the deleted chromosomal region. We now report data on five patients with the same chromosome deletion and normal activities of TPI.

The five patients were a twelve month old boy and four girls aged 2, 3½, 6, and 9 years, respectively. All patients had the characteristic clinical features of the cat cry syndrome, including the high pitched plaintive cry, microcephaly, the typical round face, ocular hypertelorism and motor-mental retardation. Acoustical measurements in the first three patients confirmed the presence of the typical physical parameters of the cry in this syndrome[2].

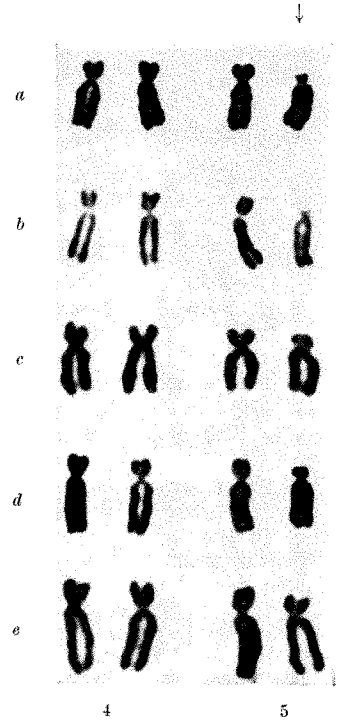

Fig. 1. *B*-group chromosomes from one cell of each patient. The deletion varies between individuals. The member of pair 5 indicated by arrow is affected. (*a* = A. K., *b* = B. S., *c* = A. P., *d* = C. H., *e* = S. G.).

Chromosomal preparations were derived from lymphocytes cultured for 72 h using a modified microtechnique[3]. A partial deletion of the short arm of a *B*-group chromosome was present in all cells of the five patients (at least twenty-five metaphases were examined by microscopy in each case). The deletions differed in size and the apparent loss of chromosomal material ranged from about 80 to 20 per cent of the short arm as shown in Fig. 1. Autoradiographic studies established the identity of the chromosome affected as number 5 in the first three patients. The characteristic phenotype and the similarities of these patients leave no doubt, however, that their deletion involves chromosome 5. The karyotypes of the parents of four patients were normal, but the mother and the maternal grandfather of patient 4 were carriers of a balanced reciprocal translocation between the part of the short arm that is deleted in the child and an autosome not yet identified, presumably a member of group *C*.

The activity of red cell triosephosphate isomerase was determined by a modification of the method of Beisenherz[4]. The results, indicated in Table 1, show that all patients and their parents had normal activities of this enzyme. Other red cell enzymes had normal activities (glutathione reductase, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, hexokinase, phosphoglucomutase, glucosephosphate isomerase, 6-phosphofructose kinase, aldolase, glyceraldehyde-3-phosphate dehydrogenase, 3-phosphoglycerate kinase, monophosphoglycerate mutase, enolase, pyruvate kinase, lactate dehydrogenase). This indicates that no overall elevation of erythrocyte enzyme activity was present which could have accounted for a spurious normal level of TPI activity. We did not perform starch gel electrophoresis because no distinct electrophoretic differences exist between the enzyme of normal homozygotes and that of persons heterozygous for TPI deficiency[5]. Other gene markers that failed to show the usual inheritance or non-paternity were: Gc, Gm, Hp, red cell acid phosphatase, phospho-

2,4-Dimethyl-3-ethylpyrrole is a highly reactive compound

glucomutase, adenylate kinase, adenosine deaminase and C'3 complement (analysed by electrophoresis), and ABO, CcDEe, Cw, MNSs, Fy, P, K and Cellano (analysed by serological methods). Sparkes *et al.*[1] argued that failure to confirm their findings would not necessarily rule out the localization of the gene for TPI on the short arm of chromosome 5, because the length of the deleted segment differs between patients. But the normal activities of TPI in our five patients occurred in deletions of different sizes, and in at least one patient the deletion was larger than described by Sparkes *et al.* Clinically it seems to make little difference whether the deletion is large or not. Our results indicate that the localization of the gene for triosephosphate isomerase on the short arm of chromosome 5 is unlikely.

This investigation was supported in part by grants from the Stiftung Volkswagenwerk, the Deutsche Forschungsgemeinschaft, and the Bundesministerium für Wissenschaft und Bildung.

Is Inactivation of the *X* Chromosome in the Female Mule Non-random ?

HAMERTON *et al.*[1] have presented evidence which they interpret as a demonstration of preferential late replication of the donkey *X* chromosome (paternal *X*) in the female mule complement. This is in disagreement with cytological evidence[2] for random *X*-inactivation[3] in the female mule complement. This apparent contradiction prompted us to repeat the latter study and we report here our observations.

According to the available information, the *X* chromosome, which replicates its DNA later than all other chromosomes in a mammalian female complement, is that which becomes genetically inactivated during embryogenesis. The hypothesis of random inactivation of the maternal (X^M) or paternal (X^P) *X* chromosome could therefore be tested in a mammalian species whose two *X* chromosomes in a female complement are morphologically distinguishable. The female mule complement is unique in that its X^M (from the horse) and X^P (from the donkey *X*) can be distinguished morphologically[4].

Fibroblast cultures were established from the skin biopsy of a female mule. Two samples of peripheral blood were obtained from a second animal at two different times for lymphocyte culture, but both cultures failed to grow. Tritiated thymidine (^{3}H-TdR, specific activity 10 Ci/mmole, New England Nuclear Corp.) was added to exponentially growing fibroblast cultures in a final concentration of 1 μCi/ml. of culture medium. Colchicine was added 1 h later. Four hours after the addition of ^{3}H-TdR the cells were collected from the medium which still contained isotope. Only well spread metaphase figures with all sixty-three chromosomes were photographed and used for this experiment (317 in all), because one medium sized acrocentric chromosome of the mule complement completes replication only slightly earlier than the late *X*, and it could easily be mistaken for the late X^P chromosome in an incomplete figure in which both *X* chromosomes or the late X^M had been lost. Kodak NTB3 emulsion was applied to each slide, and they were exposed for seven days. Metaphase figures photographed before the application of emulsion were rephotographed at the focal plane of the overlying silver grains. Only metaphase figures with a single heavily labelled *X* chromosome (that is, an *X* chromosome with at least half the total number of grains as all other chromosomes of the complement combined) were used (119 in all) for this study (Fig. 1). The relative frequencies of metaphase figures containing a late replicating X^P or X^M were 57·9 and 42·1 per cent respectively.

These results are in accord with the previous results obtained with cultured lymphocytes[2], and confirm unequivocally that either the X^P or X^M can be the late replicator in different cells of the same animal. The relative frequencies of figures with late replicating *X* or X^M obtained from this experiment varied slightly from the previous results[2] (X^P, 51·5 per cent; X^M, 48·5 per cent) but varied significantly from the frequencies reported by Hamerton *et al.*[1] (X^P, 88–100 per cent; X^M, 0–12 per cent). Although 100 per cent of the fibroblast cells from one animal in that study were found to contain a late X^P (only eight figures were examined), only 88 per cent of the lymphocytes of the same animal had a late X^P chromosome. Furthermore, the *X* linked glucose-6-phosphate dehydrogenase (G-6-PD) isoenzyme patterns of both lymphocytes and fibroblast cells observed in this study showed that the paternal G-6-PD was at least "weakly represented". These observations suggest that cells with a late X^P are more abundant than those with a late X^M in the tissues studied, but do not support the conclusion[1] that inactivation of *X* in the female mule is non-random. It should be pointed out that according to the single active-*X* hypothesis[3] one of the two *X* chromosomes in a mammalian female complement becomes genetically inactivated early in development, possibly at implantation. The cells examined in these experiments[1,2] were those at the end of the line of differentiation, far removed from their cells of origin in which random inactivation of one *X* chromosome occurred. The frequency of distribution of cells with inactivated X^P and X^M in any given tissue would depend on the distribution and selection of these two cell types during differentiation of such tissue. The fact that the relative frequency of figures

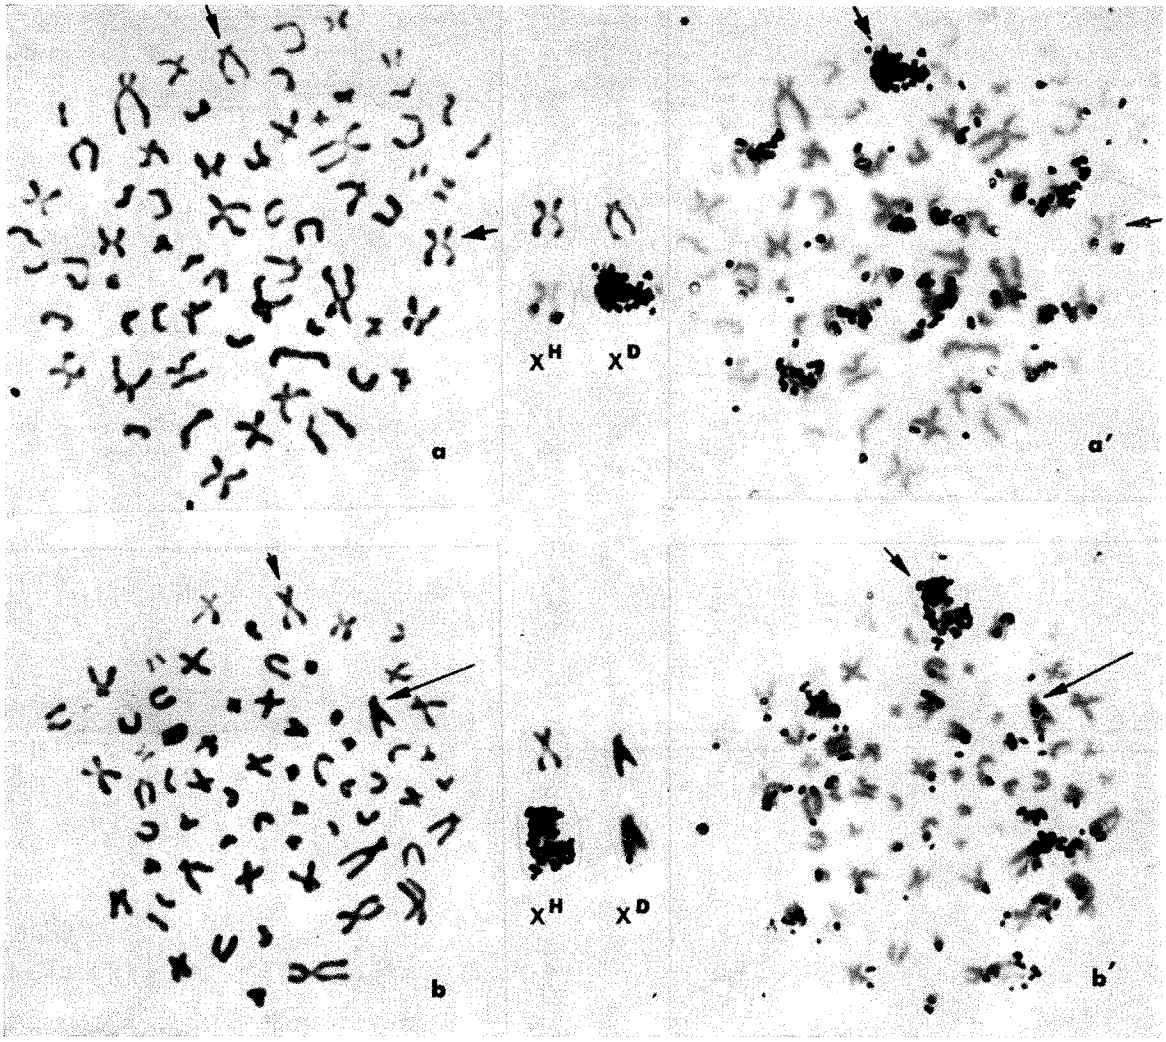

Fig. 1. Representative metaphase figures (*a* and *b*) and the corresponding autoradiographs (*a'* and *b'*). The X^P is the late replicating X chromosome in the upper figure but X^M is late in the lower figure.

with late replicating X^P or X^M varies between different tissues of the same animal and also between animals supports our conclusion.

We thank Mrs Kristine Mann-Kullberg, Mr Robert Bernstein, Mr George Kasupski and Dr Rene Milet for helpful criticism and Dr J. M. Baker for mule tissues. We also thank Miss Jane Hardwick for technical assistance and Miss Carolyn Johnston for editorial assistance.

Non-random Inactivation of the *X* Chromosome in the Female Mule

WE were interested that Mukherjee *et al.*[1] have a further mule in which the donkey X chromosome (X^P, X^D of our report)[2] is late replicating in 50 per cent of the cells. This is in agreement with the report by Mukherjee and Sinha[3] and at variance with our findings[2]. We were extremely careful not to speculate on the significance of our observations[2], and although we stressed that our findings suggested preferential activity of the paternal X we refrained from speculating about the origin of this phenomenon in "either inactivation or subsequent cell selection". We agree that cell selection between inactivation and the time when we looked at the cells could account for our results. If this is so it is extremely interesting that in our three animals strong selective pressures seemed to favour activity of the $X^M(X^D)$ as opposed to the $X^P(X^H)$. We believe that our alternative hypothesis[2] could equally account for our results. It is interesting that in the animal studied by Mukherjee *et*

al.[1] 57·9 per cent of cells had a late replicating X^P, while 42·1 per cent had a late replicating X^M. Although this distribution is significantly different from ours and not significantly different from 50 per cent, it reveals a similar trend. It is a pity that they[1] do not report results on glucose-6-phosphate dehydrogenase isoenzyme patterns for this animal.

It is important to consider whether cytological support for the Lyon hypothesis can come from random inactivation of the two morphologically distinct X chromosomes of the mule as judged by autoradiography. We believe that it may not be justified automatically to extend the concept of random inactivation of either the X^M or X^P to interspecific hybrids. In situations when the two X chromosomes are not strictly homologous, for example, Searle's translocation in the mouse and certain structurally altered X chromosomes in man, the random nature of X inactivation breaks down. Even structurally normal X chromosomes may display non-random activity in some adult tissues[4]. This is apparently dependent on which of the two alleles they are carrying[4]. Ohno[5] has shown that in certain interspecific hybrids the hybrid condition can pose considerable problems in gene regulation. In the female mule, however, there is no evidence that the two X chromosomes are strictly homologous, nor can this be postulated confidently. If this is correct, their patterns of late replication might not be expected to be random. For this reason the mule cannot be used to provide a simple cytological test for the postulate of random inactivation, even disregarding objections which could be raised concerning uneven post-inactivation cell distribution, cell selection and balance. The mule, however, provides useful material for the study of the relationship between late replication of one or other X chromosomes and gene inactivation. This was the principal object of our study.

In brief, the relationship between the autoradiographic data on the mule X chromosomes and the Lyon hypothesis are represented in algebraic form as

$$\frac{A_1Z_1L_1}{A_2Z_2L_2} = p$$

where L is the probability that one of the two homologous X chromosomes is inactivated in a female cell; A is the probability of progeny resulting from a female mule cell with one or other of the two X chromosomes active; Z is the probability that one or other of the two female mule X chromosomes is inactivated early in embryogenesis; 1 and 2 specify one of the two X chromosomes of normal female mammals, and p is a ratio of cells showing the donkey and horse X chromosome differentially labelled in the late S phase.

The values of A and Z are not known, and so the equation cannot be solved for L and it is impossible to test whether $L_1 = L_2 \sim 0{\cdot}5$ as suggested by the Lyon hypothesis.

But, if $L_1 = L_2 \sim 0{\cdot}5$ is taken for granted, inferences can be made about the products A_1Z_1 and A_2Z_2. We hope that data will become available about the value of A and Z. At present, if $P = 0{\cdot}5$ as found in two female mules[1,3], then $A_1Z_1 = A_2Z_2$. This suggests that the donkey and horse X chromosomes are equivalent with regard to the mechanism responsible for X chromosome repression or derepression, and with regard to the selective value that the activity of one or other of these two chromosomes confers on the cells. On the other hand, our data for three mules[2] and unpublished results for five further hybrids suggest that the two parental X chromosomes differ in one, the other or both of these respects, for the cells with a late labelling X^M are in a minority in all hybrids which we have studied.

We do not know the reason for the difference between our findings and those of Mukherjee *et al.*[1,3]. If it does not rest on differences of technical or analytical procedures it could have a biological meaning, perhaps in terms of "strengths" (or even homology) of the X chromosomes in two geographically distinct populations of mules.

Production of Heterologous Cytotoxic Antibodies *in vitro*

THE possibility of inducing an immunological response *in vitro* to viral[1], erythrocyte[2,3] and tissue[4-6] antigens has recently been the subject of much research. Ginsburg and Sachs[4] have shown the destructive activity of rat spleen cells stimulated *in vitro* with mouse embryo cells and proved the immunological nature of this phenomenon, but they found no activity in the tissue culture medium of these spleen cells cocultivated with mouse embryo cells. Interestingly, in these experiments the medium was harvested in the presence of mouse tissue which could have absorbed antibodies specific to mouse antigens; and, the culture medium was tested without adding complement, a substance shown to be necessary for the detection of cytotoxicity of antibodies induced *in vivo*.

We here report an investigation on a mouse–hamster system. The maturation of the immunological response was accomplished in the absence of stimulating antigen. The activity of the medium was tested by a modification of the colony inhibition (CI) technique of Hellström and Sjögren[7], using fresh guinea-pig serum as a source of complement.

The spleen from one adult female C57BL mouse was cut in small pieces and placed on the top of a 48-h-old monolayer of SV40-transformed hamster cells (designated F5-1) growing in a 10 cm Petri dish. For each experiment three or four Petri dishes were prepared. Eagle's minimum essential medium supplemented with 10 per cent foetal calf serum was used as a cultivation medium. After 1–2 days of incubation at 37° C in 5 per cent CO_2 atmosphere, the floating pieces of spleen tissue, together with spleen cells, were removed, sedimented by centrifugation, resuspended in fresh medium and put on a 24 h old feeder layer of syngeneic C57BL fibroblasts. After incubation for 4–5 days in similar conditions, the fluid was removed and the cells were sedimented by centrifugation for 30 min at 2,000 r.p.m. The activity of this cell-free medium was tested by CI assay. Medium from spleens cultivated in the same way, but in the absence of antigenic stimulation (F5–1), served as control. To 0·1 ml. of cell suspension containing 500 to 1,000 target cells was added 0·1 ml. of experimental medium, and the reaction mixture (F5–1) was incubated for 1 h at 37° C in CO_2 atmosphere, after which 0·2 ml. of undiluted guinea-pig serum was added and the incubation was continued for 30 min. The same experimental medium (12 ml.) was then added and 4 ml. distributed to each of three plastic Petri dishes and incubated for 5–7 days at 37° C in 5 per cent CO_2. The dishes

Table 1. THE COLONY INHIBITION ACTIVITY OF MEDIUM FROM MOUSE SPLEEN TISSUE STIMULATED *in vitro* BY HAMSTER CELLS

Medium used	Target cells	No. colonies (av.) Expt 1	Expt 2
Anti F5–1	F5–1	0, 0, 0 (0)	0, 3, 3 (2)
Control	F5–1	87, 86, 105 (93)	67, 93, 94 (85)
Anti F5–1	BHK	0, 0, 0 (0)	0, 0, 0 (0)
Control	BHK	148, 104, 109 (120)	97, 117, 110 (108)

were then fixed and stained with Giemsa and the colonies were counted.

The results, presented in Table 1, show that the medium from spleen tissue stimulated by F5–1 cells inhibited not only the growth of F5–1 cells, but also the formation of colonies of baby hamster kidney (BHK–21) cells; it had no effect on the ability of methylcholanthrene-induced mouse sarcoma cells to form colonies. These data indicate that the activity of the medium is directed indiscriminately against antigens of either F5–1 or BHK hamster cells.

Table 2. THE SPECIFICITY OF THE IMMUNE MEDIUM FROM MOUSE SPLEEN TISSUE STIMULATED *in vitro* BY HAMSTER CELLS (F5–1)

Medium used	Target cells	No. colonies (av.)
Anti F5–1	F5–1	1, 0, 3 (1)
Anti F5–1, absorbed by F5–1	F5–1	65, 91, 93 (73)
Anti F5–1, absorbed by BHK	F5–1	85, 55, 62 (67)
Control	F5–1	87, 81, 105 (91)

Table 3. COMPLEMENT DEPENDENCE OF THE COLONY INHIBITION ACTIVITY OF A MEDIUM FROM MOUSE SPLEEN TISSUE STIMULATED *in vitro* BY HAMSTER CELLS (F5–1)

Medium used	Target cells	No. colonies (av.)
Anti F5–1 + C^1	F5–1	3, 0, 4 (2)
Control + C^1	F5–1	69, 83, 71 (74)
Anti F5–1 (inactivated)	F5–1	59, 71, 83 (70)
Anti F5–1 (inactivated) + C^1	F5–1	7, 7, 11 (8)

For further analysis the active medium was absorbed with approximately 100 mg of either F5–1 or BHK cells for 1 h at 4° C, and the supernatant fluids were assayed by the CI test. The results (Table 2) demonstrated that both F5–1 and BHK cells were able to absorb the component in the medium responsible for colony inhibition. These data reinforce the conclusion that the activity of this medium is directed against an antigen common to hamster cells. Table 3 shows the results of an experiment designed to determine the complement dependency of this reaction. It is clear from these data that heat-inactivated medium showed no activity in the CI test. The inhibitory activity of this medium could, however, be fully restored by addition of fresh guinea-pig serum.

Effect of Mineral Adjuvant on Lymphocyte Cooperation in the Secondary Antibody Response to a Hapten–Protein Conjugate

THE determinants of the hapten and the protein carrier cooperate in the initiation of the primary antibody response to hapten–protein conjugates. Benacerraf and his colleagues[1] demonstrated that deoxynucleoprotein–polylysine alone does not elicit a primary response in certain strains of guinea-pigs, but DNP–polylysine complexed to bovine serum albumin elicits a vigorous response to the determinants of the albumin and DNP moieties. Similar findings were reported by Rajewsky and Rottländer[2] in rabbits using isoenzymes of porcine lactate dehydrogenase, and by Schierman and McBride[3] in chickens using chicken erythrocyte isoantigens. Further studies[4,5] demonstrated that the determinants of the hapten and carrier also cooperate in the initiation of the secondary antibody response of rabbits to hapten–protein conjugates; and synergy is manifested between cells primed to the carrier and cells primed to the hapten in the adoptive immune response of X-irradiated mice to NIP–protein conjugates[6], so establishing a cellular basis for cooperation between carrier and hapten in the secondary response.

Hitherto, hapten–protein conjugate in adjuvant has been used for the primary immunizations and the soluble conjugate for the secondary challenge. The object of this experiment was to determine if cell cooperation in the adoptive immune response to a hapten–protein conjugate is altered by adsorption of the conjugate to the surface of a particulate mineral adjuvant, alum, for the secondary challenge. In particular, we tested the ability of thoracic duct cells from donors immunized to diphtheria toxoid (DT) or to DNP–bovine serum albumin (DNP–BSA) to cooperate in the restoration of the antibody response of irradiated rats to DNP–DT adsorbed to alum or to DNP–DT in aqueous solution. DNP–DT was used as the conjugate because thoracic duct cells from normal (unimmunized) donors restore a negligible antibody response to the carrier and hapten portions of the alum adsorbed complex[7].

Inbred Lewis rats (Microbiological Associates) weighing 150–200 g and immunized to DT, DNP–DT or DNP–BSA were used as thoracic duct cell donors. Coupling of DNP to DT (supplied by the Commonwealth of Massachusetts Department of Health) or BSA (Nutritional Biochemicals) was accomplished with sodium 2,4,dinitrobenzene sulphonate (technical grade, Eastman)[8]. The number of DNP groups bound per molecule of protein was determined spectrophotometrically[9]. The coupling reaction was stopped by repeated dialysis of the reaction mixture against distilled water. The composition of the conjugates was DNP_{11}–DT and DNP_{23}–BSA. Adsorption of the DNP–DT and DT to precipitated alum was performed according to the method of Williams and Chase[10]. Approximately 10 mg of alum was used to adsorb 1 mg of protein.

Immunization to DNP–DT or DT was achieved by the subcutaneous and intraperitoneal injection of 0·5 ml. alum suspension to give a total dose of 0·1 mg of protein. Rats were immunized to DNP–BSA in complete Freund's adjuvant (Difco Laboratories) by the injection of 0·1 ml. of emulsion into each hind foot pad to give a total dose of 0·4 mg protein. The thoracic duct of immunized donors was cannulated by a modification of the method of Bollman *et al.*[11] 4–8 weeks after the injection of antigen. Recipients of thoracic duct cells were challenged with a single intraperitoneal injection of 0·5 mg DNP–DT in 0·5 ml. phosphate buffered saline or with a subcutaneous and intraperitoneal injection of 0·1 mg alum adsorbed DNP–DT as described.

Antibody titres were determined by a modification of the Farr technique[12]. Five-fold serial dilutions of antiserum were made in 10 × 75 mm test tubes in 0·4 ml. of 10 per cent normal rat serum. Thereafter, 0·1 ml. of 1×10^{-8} M [^{3}H]DNP–ethylaminocaproic acid ([^{3}H]DNP–EACA; supplied by Dr R. Asofsky, National Institute of Allergy and Infectious Diseases) was added to each tube. [^{3}H]DNP (New England Nuclear Corp.) was coupled to EACA by the method of Green *et al.*[13]. The test tubes were shaken and allowed to stand for at least 1 h at room temperature. Globulins were precipitated by the

addition of 0·5 ml. saturated ammonium sulphate solution to each tube. After 1–2 h the precipitates were spun down and 0·1 ml. of the supernatant was counted in a liquid scintillation spectrometer. Antibody titres were taken as that dilution of antiserum which bound 33 per cent of the labelled antigen. Groups of six animals were used to obtain mean antibody titres.

Table 1. ADOPTIVE ANTIBODY RESPONSE* TO DNP FOLLOWING A SINGLE INTRAPERITONEAL INJECTION OF 0·5 mg DNP–DT IN AQUEOUS SOLUTION

No. thoracic duct cells transferred to irradiated host (antigen used to immunize donor)	Days after injection of DNP–DT 7	14
50×10^6 (DT)	$<0\cdot1$	$0\cdot29\pm0\cdot21$
50×10^6 (DNP–BSA)	$0\cdot10\pm0\cdot12$	$1\cdot06\pm0\cdot45$
25×10^6 (DT)+25×10^6 (DNP–BSA)	$1\cdot22\pm0\cdot05$	$2\cdot48\pm0\cdot30$
50×10^6 (DNP–DT)	$3\cdot21\pm0\cdot15$	$3\cdot22\pm0\cdot13$

* Expressed as $\log_{10}$ mean antibody titre ±s.e. which bound 33 per cent of antigen ([^{3}H]DNP–EACA).

Table 1 shows the antibody response to DNP–DT in Lewis rats given 500 rad, whole body X-irradiation, and an intravenous injection of thoracic duct cells 2 h later. DNP–DT in aqueous solution was injected intraperitoneally 24 h after irradiation. A vigorous antibody response (titre > 3 $\log_{10}$ units at 7 days) was restored by 50×10^6 thoracic duct cells from donors immunized to DNP complexed to the homologous carrier (DNP–DT). The responses restored by an equal number of thoracic duct cells from donors immunized to the free homologous carrier (DT) or to DNP complexed to a heterologous carrier (DNP–BSA) were barely detectable at 7 days. The latter cells restored a moderate response by 14 days. The response restored by a combination of cells from donors immunized to DT or to DNP–BSA was much greater than the sum of the responses restored by each cell type independently. It is of interest that the response restored by the combination of cells was not as great as that restored by cells from donors immunized to DNP complexed to the homologous carrier (DNP–DT) alone.

Similar experiments in which the irradiated hosts were challenged with alum adsorbed DNP–DT instead of DNP–DT in aqueous solution showed that thoracic duct cells from donors immunized to DNP–DT restore a vigorous response again, and cells from donors immunized to DT restore a feeble response (Table 2). By day 9, however, the response restored by cells from donors immunized to DNP–BSA was similar to that restored by cells from donors immunized to DNP–DT. Further, 50×10^6 DNP–BSA primed cells produced a greater response than a combination of 25×10^6 DNP–BSA and 25×10^6 DT primed cells. These findings indicate that DNP–BSA primed cells are considerably more effective in restoring the response to DNP–DT adsorbed to alum than to DNP–DT in aqueous solution.

Table 2. ADOPTIVE ANTIBODY RESPONSE* TO DNP FOLLOWING A SINGLE INTRAPERITONEAL AND SUBCUTANEOUS INJECTION OF 0·1 mg ALUM ADSORBED DNP–DT

No. of thoracic duct cells transferred to irradiated host (antigen used to immunize donor)	Days after injection of DNP–DT 7	9	14
50×10^6 (DNP–DT)	$1\cdot66\pm0\cdot14$	—	$2\cdot39\pm0\cdot12$
10×10^6 (DNP–DT)	—	$0\cdot81\pm0\cdot38$	$0\cdot98\pm0\cdot25$
50×10^6 (DNP–BSA)	$0\cdot92\pm0\cdot23$	$2\cdot24\pm0\cdot30$	$2\cdot25\pm0\cdot23$
10×10^6 (DNP–BSA)	$0\cdot18\pm0\cdot14$	$0\cdot29\pm0\cdot13$	$0\cdot59\pm0\cdot26$
25×10^6 (DT)+25×10^6 (DNP–BSA)	—	$1\cdot63\pm0\cdot31$	$1\cdot67\pm0\cdot28$
50×10^6 (DT)	—	$<0\cdot1$	$0\cdot35\pm0\cdot22$
50×10^6 (DNP–BSA)†	$<0\cdot1$	$0\cdot46\pm0\cdot19$	$0\cdot58\pm0\cdot29$

* Expressed as $\log_{10}$ mean antibody titre ±s.e. which bound 33 per cent of antigen ([^{3}H]DNP–EACA).

† Recipients received an intraperitoneal and subcutaneous injection of 0·1 mg alum adsorbed DT and an intraperitoneal injection of 0·5 mg DNP–DT in aqueous solution.

A possible explanation of these findings is that alum adsorbed DNP–DT rapidly transforms some of the thoracic duct cells from donors immunized to DNP–BSA into carrier (DT) primed cells. Thus carrier primed cells may be present in sufficient numbers to augment the response to DNP–DT, even when they are not injected into the irradiated host. To investigate this point, irradiated hosts were given 50×10^6 thoracic duct cells from donors immunized to DNP–BSA and were challenged with an intraperitoneal and subcutaneous injection of 0·1 mg alum adsorbed DT and an intraperitoneal injection of 0·5 mg DNP–DT in aqueous solution 6 h later. Table 2 shows that the response elicited by the combined challenge was minimal, indicating that the adsorption of DNP–DT to alum does not result in the production of large numbers of carrier primed cells.

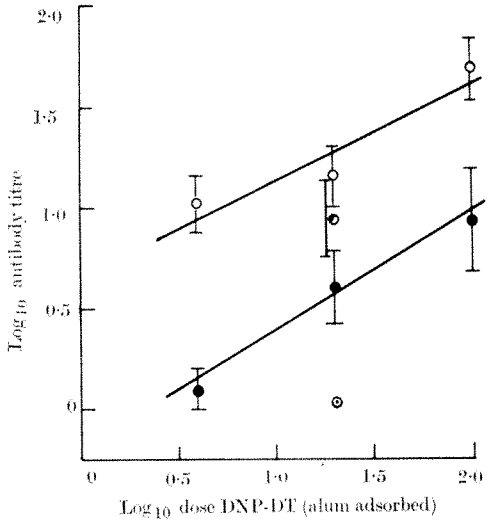

Fig. 1. Adoptive antibody response of irradiated hosts reconstituted with thoracic duct cells. Each point represents the $\log_{10}$ mean antibody titre ±standard error of the mean which bound 33 per cent of antigen ([^{3}H]DNP–EACA). The dose of alum adsorbed DNP–DT is expressed as the $\log_{10}$ μg protein injected. Antibody titres were measured 7 days after the injection of antigen. ●, Mean response restored by 50×10^6 cells primed to DNP–BSA; ○, mean, response restored by 50×10^6 cells primed to DNP–DT; ○, mean response restored by 50×10^6 cells primed to DT; ◐, mean response restored by a combination of 50×10^6 cells primed to DNP–BSA and 50×10^6 cells primed to DT.

To determine if the relative restorative action of the cell types noted in Table 2 is dependent on the dose of DNP–DT, several experiments were performed using lower doses of antigen for the secondary challenge. Fig. 1 compares the antibody response restored by DNP–DT and DNP–BSA primed cells at day 7 for three doses of the alum adsorbed antigen. The double logarithmic plots for both cell types are parallel. This shows that the relative restorative action of the two cell types is constant over the range of antigen doses tested. Further, the difference between the titres restored by the two cell types (about 0·75 $\log_{10}$ units) is considerably smaller than that noted when DNP–DT in aqueous solution is used as antigen (> 3 $\log_{10}$ units).

In further experiments, DNP–BSA and DT primed cells were tested for their ability to cooperate in the restoration of the secondary antibody response to alum adsorbed DNP–DT. Fig. 1 shows that the mean antibody titre restored by a combination of 50×10^6 DNP–BSA and 50×10^6 DT primed cells is greater than the sum of the responses restored by 50×10^6 DNP–BSA or 50×10^6 DT primed cells alone. But the difference between the means is not statistically significant ($P>0\cdot05$) according to the Student t test. On the other hand, the antibody response restored by a combination of DNP–BSA and DT primed cells was significantly greater ($P<0\cdot001$) than the sum of the responses restored by either cell type alone when DNP–DT in aqueous solution is used as antigen.

It is not clear how the addition of carrier primed cells or the adsorption of antigen to alum assists hapten primed cells to initiate the antibody response to the hapten–protein conjugate. The carrier primed cells may bind the conjugate to the cell surface producing antigen coated particles which are similar to the antigen coated alum particles and such antigen coated surfaces

may facilitate the presentation of haptenic determinants to the hapten primed cells, so helping these cells to initiate the antibody response. The carrier primed cells may function much like an adjuvant, and play a direct part in the "processing" of antigen and a more indirect part in immune recognition of the haptenic determinants.

Allogeneic Inhibition in Thymectomized Animals lacking Homograft Reactivity

THE phenomenon of allogeneic inhibition, a term coined by Hellström[1], was first observed by Snell *et al.*[2,3]. These investigators noted that certain mouse lymphoma tumours grew less well in semi-syngeneic F_1 hybrid mice than in the original parental strain. Hellström[1,4] demonstrated that carcinoma and sarcoma growth was also inhibited in semi-syngeneic hosts. He thought it unlikely that the phenomenon was caused by a graft versus host reaction leading to "allergic death" of the tumour cells; or that allogeneic inhibition was caused by a homograft reaction directed against hypothetical recessive isoantigens of the tumour[4], because all histocompatibility antigens of the mouse are codominantly expressed and F_1 hybrid mice are therefore genetically tolerant to parental strain grafts[5,6].

The mechanism of allogeneic inhibition remains obscure. Hellström *et al.*[7] and Möller[8] proposed that the *in vitro* cytotoxic effect of normal F_1 hybrid lymphoid cells on parental type target cells, and growth inhibition *in vivo*, was caused by target cell confrontation with foreign isoantigens. Alternatively, the F_1 hosts may react more efficiently against the tumour-specific antigens on the tumour cells than the parental hosts (hybrid hyperreactivity)[9–11]. It has also been suggested that the phenomenon of "hybrid resistance"[12] is related to allogeneic inhibition. It was found that the growth of haematopoietic cells from mice carrying the $H\text{-}2^b$ allele were inhibited in semisyngeneic F_1 hybrid mice. Allogeneic inhibition is not confined to $H\text{-}2^b$ cells, however, and therefore need not have a similar basis.

We have investigated whether the immunological status of the host can influence the growth of a parental tumour in a semisyngeneic F_1 hybrid host. Mice of the following inbred mouse strains, 2–4 months old, were used: A/Sn ($H\text{-}2^a$) and the F_1 hybrids (A × CBA)F_1 ($H\text{-}2^a$) ($H\text{-}2^k$) and (A × DBA) F_1 ($H\text{-}2^a$) ($H\text{-}2^d$). A Moloney virus induced ascites lymphoma indigenous to the A strain (YAC) was used throughout the experiments. Ascites fluid containing YAC cells was passaged in the A strain.

Quantitative estimates of tumour growth were carried out according to the technique developed by Lindholm *et al.* (unpublished), which measures the rate of tumour growth by the incorporation of ^{3}H-thymidine. Tumour cells injected into the experimental animals were collected from ascites fluid in pasteur pipettes, washed twice in balanced salts solution and counted in a Bürker chamber. 10^4 trypan-blue unstained cells in 1 ml. were injected intraperitoneally into each mouse. Seven days later the mice were injected with ^{3}H-thymidine (specific activity 5,000 mCi/mmole). After 2 h the mice were killed by cervical spine dislocation. Two ml. of sterile tissue culture medium (Parker '199') was injected intraperitoneally and the fluid was withdrawn. The number of tumour cells was counted under phase contrast microscopy. Smears were prepared from the fluid and were fixed in cold 95 per cent ethanol. Autoradiographs were made according to Caro and van Tubergen[13], using Ilford nuclear research emulsion type K-5. The autoradiographs were exposed for 10 days in the dark at room temperature, developed, fixed and stained through the emulsion with the methyl-green pyronin stain[14]. The percentage of tumour cells labelled with ^{3}H-thymidine was estimated from counts of 1,000 cells.

Thymectomy was performed at the age of 4–5 weeks. Ten days later they were subjected to 600 rad whole body dose of X-irradiation generated in a Siemens X-ray machine at 15 mA and 200 kV filtered by 0·5 mm Cu. Immediately thereafter $15 \times 10^6 - 20 \times 10^6$ syngeneic bone marrow cells were injected intravenously in the tail vein. Skin grafts were transplanted essentially according to the method of Billingham and Medawar[15] with slight modifications[16]. The "tolerant" state of animals so treated (adult thymectomy, X-irradiation and reconstitution with bone marrow cells) was tested with H-2 incompatible skin grafts (C57BL-($H\text{-}2^b$)). Only animals carrying healthy skin grafts at 1–2 months after grafting were used in the experiments.

The growth of 10^4 YAC ascites lymphoma cells was measured in the six following groups of animals: (1) normal syngeneic A/Sn mice, and semi-syngeneic F_1 hybrid mice; (2) syngeneic and semi-syngeneic F_1 mice that were thymectomized at the age of 4–5 weeks, at least 2 weeks before inoculation with tumour cells; and (3) syngeneic and semi-syngeneic F_1 mice that were thymectomized at 4–5 weeks, thereafter lethally irradiated and reconstituted with $10–15 \times 10^6$ syngeneic bone marrow cells immediately after irradiation. All experiments were not performed at the same time but animals belonging to the same experiment (see Table 1) were injected with the same tumour suspension. Seven days after injection of tumour cells the total number of tumour cells was estimated and the percentage of cells actively synthesizing DNA was measured by incorporation of ^{3}H-thymidine following a single intraperitoneal injection as described.

Experiments 1, 2 and 3 show that the number of tumour cells present on the seventh day of growth is not lower in A mice subjected to thymectomy or thymectomy followed by irradiation and restoration with syngeneic bone marrow cells than in untreated A mice (Table 1). The percentage tumour cells in DNA synthesis is also not reduced in treated A mice as compared with untreated A mice. On the other hand, both the number of tumour cells present on the seventh day of growth and the percentage of tumour cells in DNA synthesis are lower in all groups of F_1 animals than in A mice (experiments 3–6). Further, there is not much difference between tumour behaviour in untreated F_1 hybrids and in F_1 hybrids which have been thymectomized, or thymectomized, X-irradiated and bone marrow protected. It has been shown (L. L., and Britton, S., unpublished) that during

Table 1. GROWTH OF TUMOUR CELLS IN HOSTS

* Thx stands for thymectomy; BM = bone marrow.

Growth of 10^4 YAC ascites tumour cells injected intraperitoneally into groups of 2–4 months old syngeneic A/Sn and semisyngeneic F_1 hybrid mice. The recipients were either untreated, thymectomized as adults or thymectomized as adults, lethally irradiated and reconstituted with syngeneic bone marrow cells. On day 7 the total number of YAC tumour cells as well as the percentage of cells actively synthesizing DNA measured by ^{3}H-thymidine uptake was assayed.

allogeneic inhibition fewer YAC tumour cells are synthesizing DNA than during growth in syngeneic hosts. The results given in Table 1 therefore indicate that allogeneic inhibition of the YAC tumour is a phenomenon which is expressed also in animals incompetent to carry out cellular immune reactions.

To explain the reduced growth of parental grafts in F_1 hybrids, it has been postulated that a heterosis effect in the F_1 hybrids increases the ability of the hosts to react against the tumour-specific antigens present in the tumour. Huemer[9] recently presented data in support of this hypothesis, but these arguments lack direct experimental proof. Our findings would rule out this hypothesis, for the phenomenon could be reproduced in animals which by thymectomy and X-irradiation had been deprived of homograft reactivity to the extent that they accepted *H*-2 incompatible skin grafts. We therefore conclude that these findings substantiate the hypothesis that growth inhibition of parental strain grafts in F_1 hybrids is caused by a reaction which is independent of cellular immune reactivity of the host. Inhibition of tumour growth probably depends on tumour cell contact with foreign isoantigens present in the host tissues[7,8]. Our preliminary results suggest that growth inhibition of parental tumour grafts in F_1 hybrids depends on close contact with host cells, for no inhibition is observed with tumours enclosed in cell-impermeable diffusion chambers.

We thank Mrs Lill-Britt Andersson for technical assistance. This work was supported by grants from the Swedish Cancer Society, the Swedish Medical Research Council and the Damon Runyon Memorial Fund.

Agarose Derivatives for Purification of Protein by Affinity Chromatography

AFFINITY chromatography[1–5], which in principle is related to the use of immunoadsorbants for the purification of antibodies[6], exploits the reversible and specific interactions of ligands with macromolecules. Purification is affected by chromatographing the protein to be purified on a column containing an insoluble matrix to which the specific ligand is covalently attached. Beaded agarose ('Sepharose') is a useful insoluble support which has recently been used successfully in the selective purification of enzymes[1–5,7,9], antibodies and antigens[10–15], chemically synthesized peptides[16,17], thyroxine binding serum proteins[18], and in the study of the interaction of insulin with cell membranes[19]. In these studies the ligands or peptides were attached through their amino groups after activation of 'Sepharose' with cyanogen bromide[20,21].

Successful purification by affinity chromatography depends in many cases on placing the ligand far enough from the matrix backbone to minimize steric restrictions in the interaction between the ligand and the macromolecule to be purified[2]. This is particularly important for protein–ligand complexes of relatively weak affinity ($K_i > 10^{-4}$ M). An effective approach in these cases is to attach first a hydrocarbon extension "arm" to the solid support; the ligand is then attached to this arm.

Chemical derivatives of agarose make it possible to attach a wider range of ligands and proteins to the support, and so increase the general versatility of affinity chromatography, especially in cases where (*a*) hydrocarbon chains of varying length (arms) are to be interposed between the matrix and the ligand, (*b*) amino groups are not present on the ligand, and (*c*) it is desirable to remove the intact protein–ligand complex by specific chemical cleavage of the ligand–matrix bond. We now report methods for preparing derivatives (Fig. 1); further details will be described elsewhere[2].

Ligands containing primary aliphatic or aromatic amino groups can be coupled directly to 'Sepharose' by the cyanogen bromide procedures previously described (Fig. 1; 1)[1,2]. ω-Aminoalkyl-'Sepharose' can be prepared by reacting diamine derivatives, $NH_2(CH_2)_xNH_2$, with cyanogen bromide-activated 'Sepharose' (Fig. 1; 2). Very little crosslinking occurs if a large excess of diamine is used, so that it is easy to insert extensions of considerable length, depending on the nature of $(CH_2)_x$. The amino-'Sepharose' derivatives thus prepared are the basis of a variety of subsequent procedures.

Bromoacetyl-'Sepharose' is prepared from amino-'Sepharose' by reaction in aqueous media at neutral *p*H with O-bromoacetyl-N-hydroxysuccinimide (Fig. 1; 3). Alkylated 'Sepharose' derivatives can then be prepared by reaction with proteins, peptides, or ligands containing amino, phenolic, or imidazole substituents (Fig. 1; 4). Ligands containing carboxylic groups can be coupled directly to amino-'Sepharose' with water soluble carbodiimides (Fig. 1; 5). Amino-'Sepharose' can be treated in aqueous media, at *p*H 6, with succinic anhydride to form carboxylic-'Sepharose' derivatives (Fig. 1; 6). Primary aliphatic or aromatic amines can in turn be coupled to these with water soluble carbodiimides (Fig. 1; 7). Diazonium-'Sepharose' derivatives are prepared by treat-

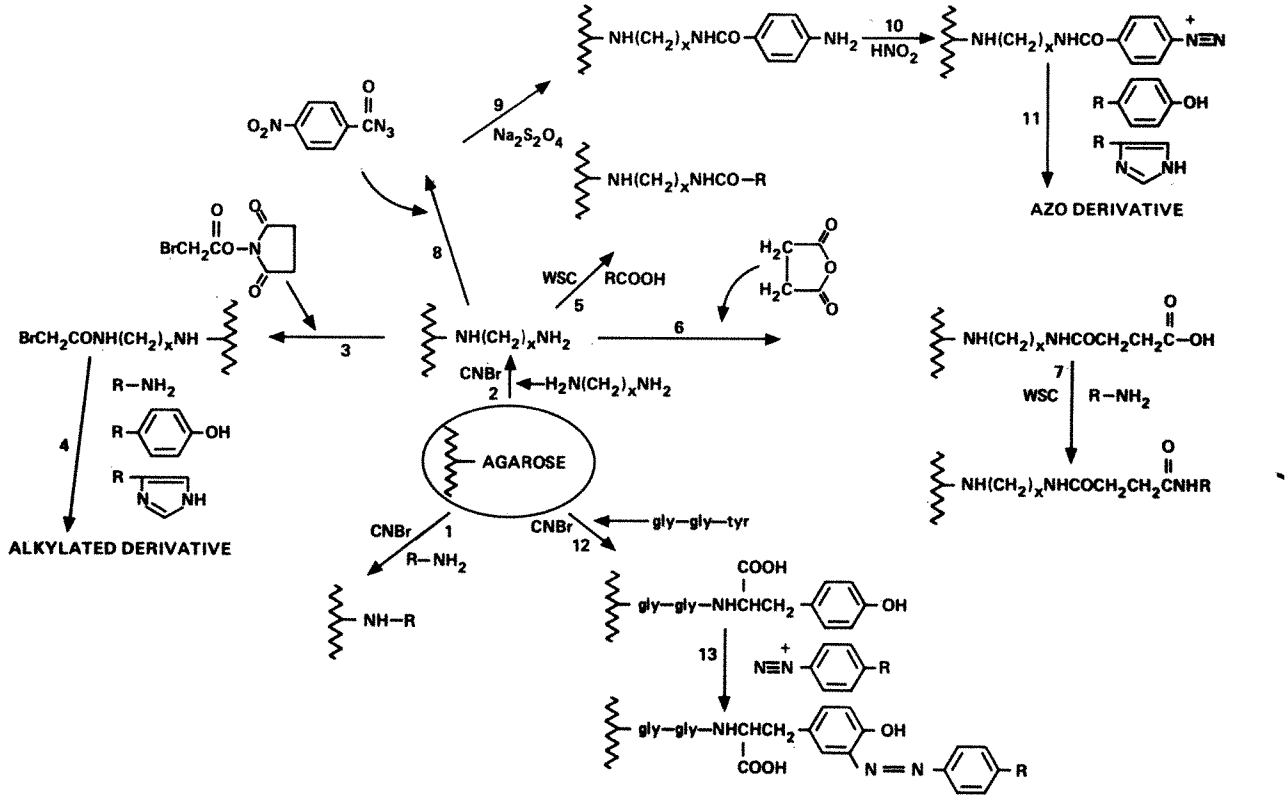

Fig. 1. Procedures for preparing derivatives of 'Sepharose 4B'.

ing amino-'Sepharose' with *p*-nitrobenzoyl azide in 50 per cent dimethylformamide (Fig. 1; 8), reduction to the aminophenyl derivative with sodium dithionite (Fig. 1; 9), and diazotization with nitrous acid (Fig. 1; 10). Ligands having phenolic or imidazole groups react rapidly with diazonium-'Sepharose' (Fig. 1; 11). Ligands that contain aromatic amino groups, which can be diazotized, can be coupled in azo linkage to a 'Sepharose' derivative which contains a covalently linked carboxy-terminal tyrosine peptide (Fig. 1; 12, 13). A special advantage of azo-linked ligands is the susceptibility to cleavage of the ligand-'Sepharose' bond by reduction with 0·1 M sodium dithionite at *p*H 8. The ligand–protein complex can thus be removed intact from a solid support which contains a selectively adsorbed protein. This form of elution may be necessary in cases where other forms of elution, such as changing the *p*H or ionic strength, or adding protein denaturants, cause irreversible inactivation of the protein.

Sulphydryl–agarose derivatives can be prepared by treating amino-'Sepharose' with N-acetylhomocysteine thiolactone at 4° C and *p*H 9·7[2]. Ligands containing free carboxyl groups can in turn be coupled to such thiol-agarose derivatives by reaction with water soluble carbodiimides. The thiol ester linkage produced can be specifically cleaved by a short exposure to *p*H 11·5, or with neutral hydroxylamine.

Many of these derivatives have been used in the purification of staphylococcal nuclease, amyloid protein, oestradiol binding serum protein, β-galactosidase, and antibodies (P. C., unpublished). In general, affinity adsorbants prepared by these procedures are superior to those prepared by attaching ligands or proteins directly to the agarose backbone by the cyanogen bromide procedure used until now. Bacterial β-galactosidase, for example, does not bind to adsorbants prepared by attaching *p*-aminophenyl-β-D-thiogalactopyranoside directly to 'Sepharose'. By contrast, strong adsorption of the enzyme occurs to adsorbants prepared by attaching the inhibitor to 'Sepharose' derivatives which contain long (20 Å) hydrocarbon "arms" (Fig. 1; 7) (Steers, jun., E., Pollard, H., and P. C., in preparation). Even where specific enzyme adsorption does occur with adsorbants prepared by direct attachment of the ligand, the total protein binding capacity is greater with adsorbants prepared from agarose derivatives which contain long hydrocarbon chains[2].

These agarose derivatives also provide alternative ways of insolubilizing peptides and proteins, which may be especially useful in the study of interactions of proteins or polypeptides with intact cells or particulate cell structures.

Cross Partition and Isoelectric Points of Proteins

AQUEOUS mixtures of dextran and polyethylene glycol give rise to liquid two-phase systems suitable for the partition of proteins[1–5]. The partition behaviour of proteins depends to a great extent on the ionic composition of the phase system and on the charge of the protein. Negatively charged materials, for example, have higher partition coefficients in sodium sulphate than in sodium chloride while the reverse holds true for positively charged materials[5,6]. It was found that when a protein was partitioned at different *p*Hs in dextran–polyethylene glycol phase systems containing two different salt compositions two curves were obtained when partition coefficients were plotted against respective *p*Hs[5]. These curves crossed close to the isoelectric point of the protein. We have now carried out such experiments on many different proteins and found the relationship between cross point and isoelectric point to be general.

The partition coefficients of four proteins at different *p*Hs in either Na_2SO_4 or NaCl are shown in Fig. 1. For each protein two curves are obtained, one for each salt, which cross. In all cases proteins have higher K values in NaCl than in Na_2SO_4 to the left of the cross point while the reverse is true to its right. The cross point is very close to the protein's isoelectric points not only for the proteins shown in Fig. 1 but also for those described in Table 1.

Ribonuclease and trypsin are exceptions. In the case of ribonuclease a line (between *p*H 7·2 and 9·7) rather than a point joins the NaCl–Na_2SO_4 partition curves. Interestingly, the literature reports widely divergent isoelectric points for ribonuclease which fall into this *p*H range. All other proteins tested show a good correspondence between isoelectric and cross points. We propose therefore that the determination of a cross point can be used to estimate the isoelectric point of a protein (Table 1).

Cross points similar to those reported here can also be obtained with other pairs of salts; for example, KCl–Li_2SO_4. The *p*H of the cross point may then shift slightly. Also, higher concentrations of salts may be used. The cross points, when NaCl–Na_2SO_4 are used, shift only slightly with ionic strength. Isoelectric points can therefore be determined for proteins which are soluble or stable only at high salt concentration and for which electrophoresis is therefore difficult.

The partition coefficient at the corresponding cross-point is only slightly dependent on the ionic composition. It may be considered to be a characteristic constant of a protein.

There is ample evidence that the partition of proteins,

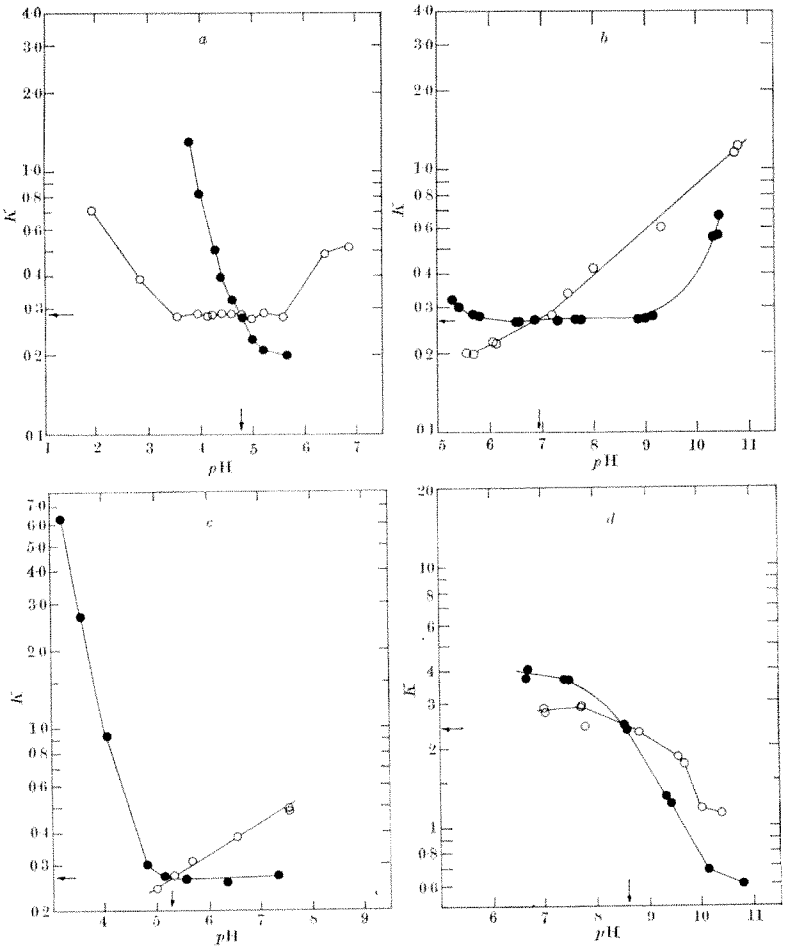

Fig. 1. Partition coefficient of proteins in two-polymer phases as a function of *p*H and two different salt compositions: (*a*) serum albumin, (*b*) haemoglobin, (*c*) transferrin, (*d*) papain. Phase system is composed of 7 per cent (w/w) dextran, 4·4 per cent (w/w) polyethylene glycol, 0·01 M buffer and either 0·1 M NaCl (●) or 0·05 M Na_2SO_4 (○). Dextran was obtained from Pharmacia, Uppsala, as 'Dextran 500'. Batch Nos. 3202, 4024 and 5996 were used interchangeably. Polyethylene glycol (PEG, 'Carbowax 6000') was obtained from Union Carbide. The procedure for preparation, partition and assay of proteins in the phases has been described[3]. Partition coefficients (K) are defined as protein absorbance at 280 nm (or 540 nm for haemproteins) in the top phase/protein absorbance in the bottom phase. Serum albumin, human, was obtained from Boehringer, Mannheim, papain was obtained from Sigma, and transferrin was a gift from Dr J.-O. Jeppson[24], Department of Medical Chemistry, Umeå.

as well as that of other polyelectrolytes, is to a great extent dependent on their charge. Thus the partition of positively charged proteins (that is, below their isoelectric points) and of negatively charged proteins (above their isoelectric points) is salt-dependent in opposite ways. In NaCl the positively charged protein has a higher partition than the negatively charged protein while in Na_2SO_4 the reverse is true. It follows that the phases behave as if the bottom (dextran-rich) phase is more negative electrically than the top (polyethylene glycol-rich) phase in Na_2SO_4 than it is in NaCl. This phenomenon may be related to the significant, though small, unequal partition of ions in these phase systems (G. Johansson, in preparation).

Effect of Free Fatty Acids on ADP-induced Platelet Aggregation

HUMAN platelets, like most mammalian cells, take up and metabolize long-chain free fatty acids (FFA)[1–3]. Unbound long-chain fatty acids are known to cause platelet aggregation which is associated with the release of adenine nucleotides and serotonin[4–6]. The purpose of this investigation was to determine whether exposure of platelets to albumin-bound FFA, in concentrations that are elevated but which can occur in physiological conditions, might affect platelet function. We have studied the influence of the FFA/albumin molar ratio ($\bar{\nu}$) on the response of platelets to adenosine diphosphate (ADP), a compound which may have an important role in haemostasis and thrombosis.

The effects of incubation of platelets with increasing concentrations of albumin-bound palmitic acid are shown in Fig. 1. As the $\bar{\nu}$ was raised, the degree and rate of aggregation induced by a standard amount of ADP increased. Aggregation is represented by an upward deflexion of the curve, and the size of aggregates is reflected by the length of the oscillations. The amount of ADP was constant in each experiment and was selected so that a definite but submaximal response occurred with the albumin solution containing no added FFA. In contrast to the results with palmitate (16 : 0), the unsaturated FFA, oleic (18 : 1) and linoleic (18 : 2) caused

Table 1. UPTAKE OF ^{3}H-PALMITATE BY HUMAN PLATELETS

FFA/albumin ratio (ν)	Total lipid	Uptake (nequiv/10^9 platelets) FFA	Phospholipid	Other
2	4·0 ±0·1	2·2 ±0·2	1·4 ±0·1	0·4 ±0·005
5	15·4* ±0·4	12·0* ±0·1	2·4* ±0·2	1·0* ±0·1

Results represent mean values ± s.e., obtained from two experiments and a total of six determinations. Incubation period was 5 min. Blood from healthy, non-fasting, human donors was drawn into Formula A–ACD in transfer packs (Fenwal Laboratories, Morton Grove, Illinois). The blood was transferred to siliconized conical tubes, and was centrifuged at 1,300 r.p.m. for 15 min at 20° C. The platelet-rich plasma (PRP) was transferred to siliconized conical tubes, and 1 ml. of 0·077 M EDTA was added for each 10 ml. of PRP. The PRP was then centrifuged at 2,500 r.p.m. for 15 min at 4° C. The platelet pellet was resuspended in a solution of 2×10^{-3} M human albumin in Tris-buffered saline containing $2{\cdot}4\times10^{-3}$ M glucose, and $1{\cdot}54\times10^{-3}$ M EDTA and then centrifuged at 1,200 r.p.m. Crystalline human albumin was obtained from Pentex Inc., Kankakee, Illinois, USA. The platelet pellet was resuspended in Tris-buffered saline containing 3×10^{-3} M glucose. Fatty acids were added to 1×10^{-4} M solutions of albumin in Tris–NaCl–KCl buffer (*p*H 7·4) (0·0154 M Tris–0·113 M NaCl–0·0057 M KCl) by the method of Spector and Hoak[7]. The FFA concentration of the resulting solution was determined by a modification of the method of Noble[8]. Unlabelled fatty acids were purchased from the Hormel Institute, Austin, Minnesota, and ^{3}H-palmitic acid was obtained from Amersham-Searle, Chicago, Illinois. Platelet aggregation was determined at 37° C using a turbidimetric method[9]. In each experiment, 0·75 ml. of the FFA-albumin mixture was incubated with 0·25 ml. of platelet suspension (containing 0·8 to 1×10^8 platelets/cm^3) for 3 min before adding 0·1 ml. of human fibrinogen[10] solution (1·5 mg/ml.). Two minutes later calcium was added (final concentration $2{\cdot}2\times10^{-3}$ M), and then ADP (1×10^{-6} to 5×10^{-4} M, final concentration) was added. A fatty acid–poor albumin solution of the same molarity was used as the control. In the uptake studies 2 ml. of ^{3}H-palmitate–albumin solution was incubated with 1 ml. of the platelet suspension containing 10^8 cells at 37° C with air as the gas phase[11]. These media contained $7{\cdot}5\times10^{-3}$ M glucose.

* Values are significantly different ($P<0{\cdot}01$) from corresponding values at $\bar{\nu}$ of 2.

little or no enhancement of aggregation even when the $\bar{\nu}$ was 6. Results obtained with stearic acid were similar to those with palmitic acid. When FFA of shorter chain length were used, less enhancement of aggregation was found. Myristic acid (14 : 0) produced a moderate enhancement of the ADP response, but lauric acid (12 : 0) had little or no effect.

The uptake of FFA by the platelets at different $\bar{\nu}$ values is shown in Table 1. At a $\bar{\nu}$ of 2, 55 per cent of the platelet lipid radioactivity was in FFA and 45 per cent was in ester forms. When the $\bar{\nu}$ was increased to 5, the incorporation of ^{3}H-palmitate into all platelet lipids increased significantly, but the greatest increase, over a five-fold rise, was in the FFA fraction. Thus the major effect of increasing the extracellular FFA concentration was to produce a marked increase in the amount of labelled palmitate incorporated into the platelet as FFA.

Only small differences have been noted in the amounts of various long-chain saturated or unsaturated fatty acids incorporated into platelet phospholipids, triglycerides or CO_2[11]. In contrast, much more saturated fatty acid was taken up by the platelet as FFA than was unsaturated fatty acid[11]. The results of our aggregation experiments indicate that fatty acids which are taken up in unesterified form to a greater extent by the platelet also produce greater enhancement of ADP-induced aggregation. In earlier studies performed with the unbound salts of fatty acids long-chain saturated FFA also produced greater platelet aggregation than did unsaturated or short-chain FFA[6].

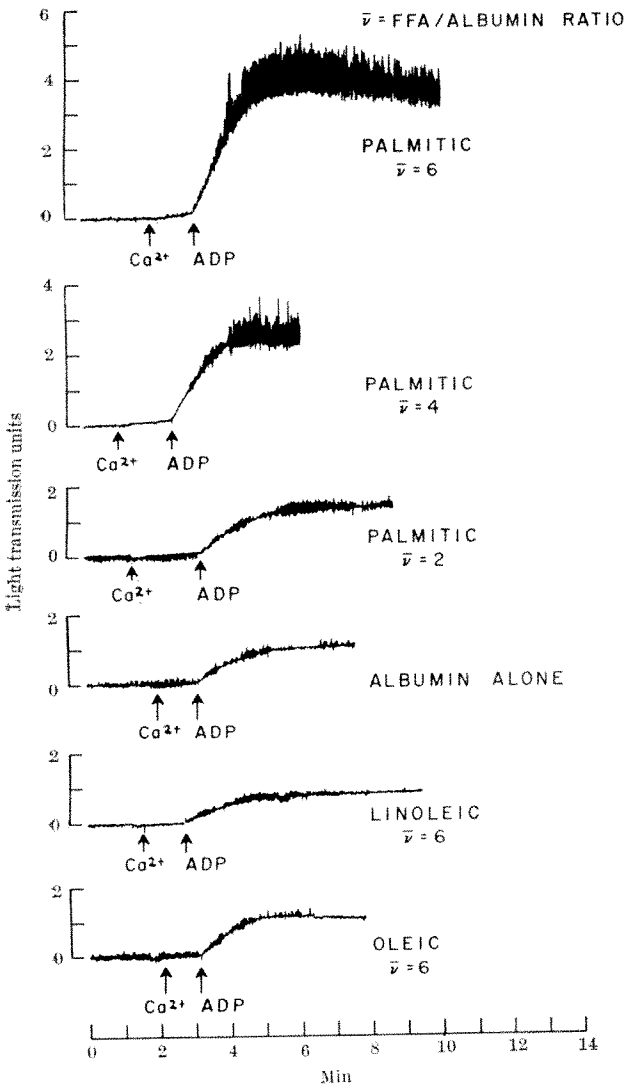

Fig. 1. Effect of albumin-bound palmitic (C16 : 0), oleic (C18 : 1) and linoleic (C18 : 2) acids on platelet aggregation induced by adenosine diphosphate (final ADP concentration added was 1×10^{-6} M). Final Ca^{2+} concentration was $2{\cdot}2 \times 10^{-3}$ M.

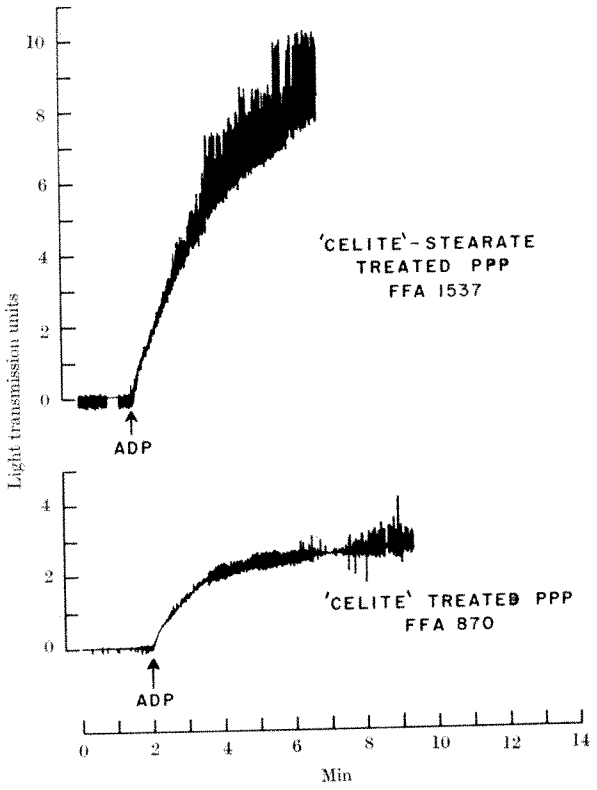

Fig. 2. Effect of high concentration of FFA in the plasma on aggregation by ADP. Donor platelets were exposed to platelet-poor donor plasma which had its FFA concentration increased by incubation with Celite' particles coated with stearic acid. After the 'Celite' was removed, the platelets were resuspended in the plasma before ADP was added. Final ADP concentration added in each experiment was $2{\cdot}5 \times 10^{-6}$ M.

In additional experiments, a mixture of FFA–albumin solutions was used with the FFA composition comparable with that found in plasma (myristic 5 per cent, palmitic 25 per cent, stearic 15 per cent, oleic 40 per cent and linoleic 15 per cent). No enhancement of aggregation was seen at a $\bar{\nu}$ of 2, but definite effects similar to those found with long-chain saturated FFA were observed when the molar ratio of total FFA to albumin was 4 or 6.

In other experiments, donor platelets were first separated from the plasma and the FFA content of the donor plasma was raised by incubation with 'Celite' particles coated with stearic acid. The 'Celite' was removed, and the platelets were then resuspended in the plasma before ADP was added. As a control, ADP was added to donor platelets resuspended in platelet-poor donor plasma that had been incubated with uncoated 'Celite'. Plasma FFA concentrations were determined on both plasma samples. Enhanced aggregation by ADP was observed only when platelets were suspended in plasma containing a high concentration of FFA (Fig. 2).

We interpret these results to indicate that exposure to a high concentration of fatty acid may alter the reactivity of the platelet and thereby enhance its responsiveness to ADP on to other agents which influence platelet function *in vivo*. The principal effect of an increase in the FFA/albumin molar ratio was to increase the FFA content of the platelet. A dynamic equilibrium state may exist between the binding of FFA by albumin and the uptake of FFA by platelets and other cellular elements. Acute lipid mobilization causing high plasma FFA concentrations or disease states in which the albumin

content or FFA binding capacity are reduced might produce a transient state in which excessive amounts of FFA associate with platelets. In this condition the platelet may develop a propensity toward aggregation which could lead to the formation of thrombi.

The enhanced aggregation of platelets related to the uptake of FFA may have relevance to variation in the response of platelets from different donors or at different time intervals in the same donor to aggregating agents; to the development of thrombocytopenia in some patients treated with heparin due to activation of plasma lipolytic activity; and to a link between stress and an increased susceptibility to thrombosis.

Genetic Content of Adult Somatic Cells tested by Nuclear Transplantation from Cultured Cells

It has yet to be proved that somatic cells of an adult animal possess genes other than those necessary for their own growth and differentiation. A particularly stringent test of the genetic content of the nucleus of a somatic cell is provided by transplanting it to an enucleated egg. The development of the egg tests the capacity of the genes in the transplanted nucleus to elicit normal early development and differentiation. Although this method has been applied to certain cells of embryos, larvae[1,2], and newly metamorphosed froglets[3], it has not been possible, until now, to transfer nuclei successfully from the cells of normal adult animals.

The experiments described here use cell cultures (Fig. 1) to obtain rapidly growing cell populations from adult organs of the frog *Xenopus laevis*. Nuclei from cultured cells are transplanted into enucleated eggs by the method described previously[4]. The results show that cells cultured from several different adult organs contain a wide range of genes which are not normally expressed in the original tissues. The development of enucleated eggs which received a transplanted nucleus is shown in Table 1. As in our previous experiments with nuclei from cultured tadpole cells[5], most eggs which received nuclei from adult organs failed to cleave or cleaved abortively to form blastomeres of irregular sizes. Most of the nuclear transplant eggs which contained a region of apparently normal cells also contained an uncleaved or abortively cleaved region. In previous experiments[5], it was observed that blastulae which are imperfect in any way usually die before the early gastrula or late blastula stages. This is true of the partial blastulae prepared from adult organ nuclei, and it is not informative to consider the development of first-transfer embryos beyond the late blastula stage.

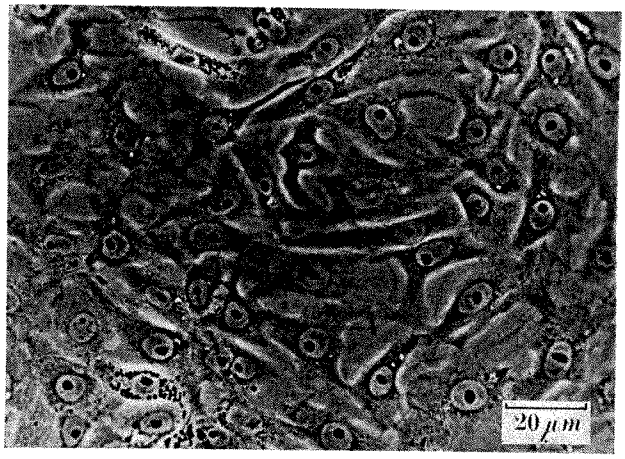

Fig. 1. Primary monolayer culture of trypsinized adult 1-*nu* kidney cells, 3 days after plating, showing only one nucleolus in each nucleus. For some experiments cultures were prepared as outgrowths from explants in fibrin clots. All cultures were maintained in modified L-15 medium[5,11].

Although partial blastulae cannot develop normally, it has been shown in previous work[1,5] that some of their cells may contain nuclei which can support normal development. The cells of a partial blastula may be dissociated and used to provide a source of donor nuclei for a second series of nuclear transfers. In this way it is possible to prepare a clone of embryos all of which contain nuclei derived by mitosis from the same original cultured cell. Nuclear transplantation sometimes results in chromosomal and developmental abnormalities[6-9]; so the most normal serial-transplant embryo within a clone provides a minimum estimate of genetic information contained in the originally transplanted nucleus.

Table 1. THE DEVELOPMENT OF EGGS RECEIVING SINGLE NUCLEI TRANSPLANTED FROM CULTURED CELLS

Source of cultured cells	Total number of nuclear transfers	Percentage cleaving to partial or complete blastulae (stage 9)* (ref. 13)
Stage 40 tadpoles	3,546	30·4†
Adult kidney	789	26·2
Adult lung	502	23·9
Adult heart	273	22·0
Adult testis	73	26·1
Adult skin	1,031	31·2

* At least half of each egg in this category cleaved completely to reach the late blastula stage.
† Data from ref. 5.

The results of serial nuclear transfers from cultured cells of various origins are summarized in Fig. 2. Two conclusions can be drawn from first as well as serial transfers. First, the development supported by nuclei from cultured cells of different origins is strikingly similar. Second, the developmental capacity of nuclei from cell cultures of adult organs closely resembles that of nuclei from tadpole cell cultures.

Before firm conclusions can be drawn concerning the gene content of a transplanted nucleus, it is necessary

to prove that the egg nucleus has not contributed to the development of the nuclear-transplant embryo. Although the reliability of ultraviolet irradiation for enucleating eggs of *Xenopus* has been demonstrated[10] it is desirable to prove that the nuclei of a transplant-embryo are the mitotic products of the transplanted nucleus and not of the recipient egg nucleus. For all the experiments described here, cell cultures have been grown from animals which are heterozygous for the anucleolate mutation[11] (1-*nu*) and therefore have only one nucleolus per diploid chromosome set (Fig. 1). All the frogs whose eggs were used as recipients for either first or serial nuclear transfers were shown to be 2-*nu* (Fig. 3) and therefore have two nucleoli per diploid chromosome set. When a 1-*nu* diploid nucleus is injected into an egg laid by a 2-*nu* frog, participation of the egg nucleus could give rise to a 1-*nu* haploid or 2-*nu* diploid. Alternatively, the combination of the egg nucleus with the injected nucleus could give rise to 2-*nu* triploids or 3-*nu* tetraploids but the egg nucleus could not contribute to 1-*nu* diploid embryos. Care must be taken in interpreting the origin of embryos which are 2-*nu*, for the nuclear transfer procedure is known to raise the normal low incidence of tetraploids[12]; these would therefore be 2-*nu* even though the transplanted nucleus is the sole source of their nuclei. In previous work[5] we have excluded the possibilities that nuclear-transplant embryos might consist of a mosaic of haploid and diploid cells, or that ultraviolet irradiation could cause the recipient egg nucleus to change from a 2-*nu* to 1-*nu* constitution.

Altogether, 5,200 eggs have received nuclei serially transplanted from adult somatic cells. It has not been possible to test the origin of the nuclei in all the embryos

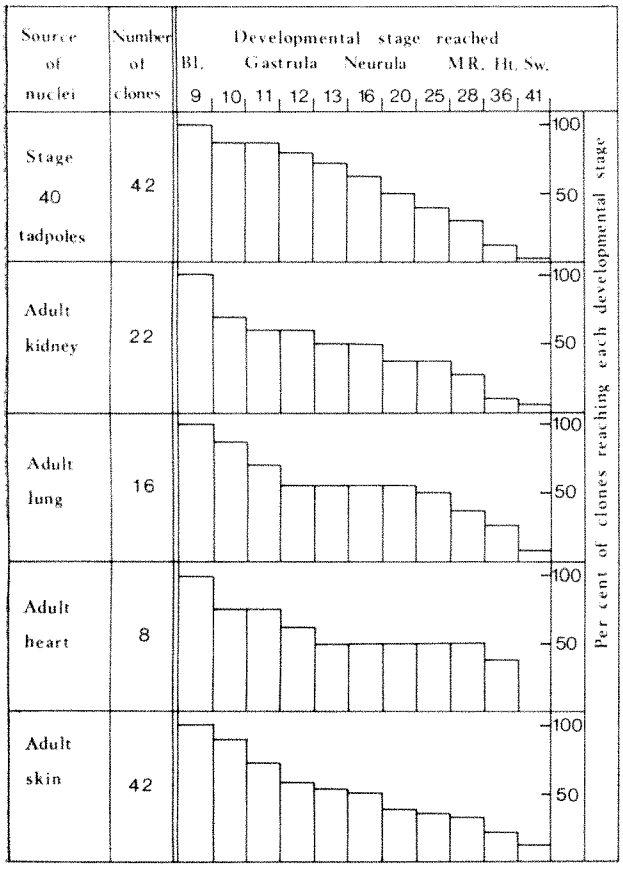

Fig. 2. The development of embryos in clones derived by serial transplantation of nuclei from cultured cells. The developmental stage reached by the most normal embryo is shown for each clone. Abbreviations: Bl, blastula; MR, muscular response; Ht, heart beat; Sw, spontaneous swimming.

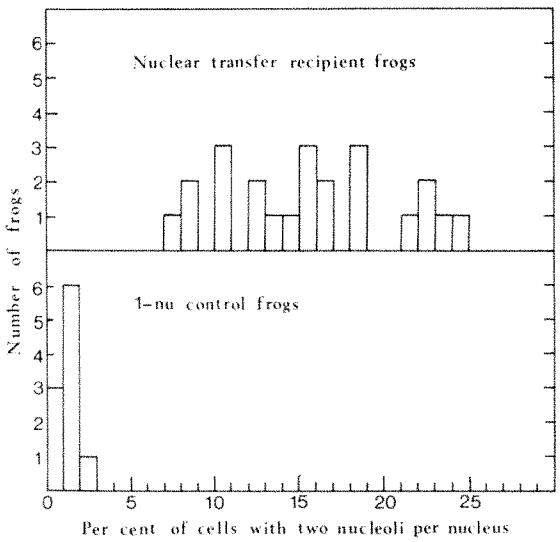

Fig. 3. The nucleolar number of frogs whose eggs were used as recipients for nuclear transfers. Skin explants from each frog were cultured in plasma clots. Five hundred cells in the monolayer outgrowth from each explant were scored to determine the percentage of cells with two nucleoli per nucleus. The histogram relates this value to the number of frogs tested. All the frogs used to provide recipient eggs were clearly different in nucleolar number from 1-*nu* controls, as expected of wild type frogs.

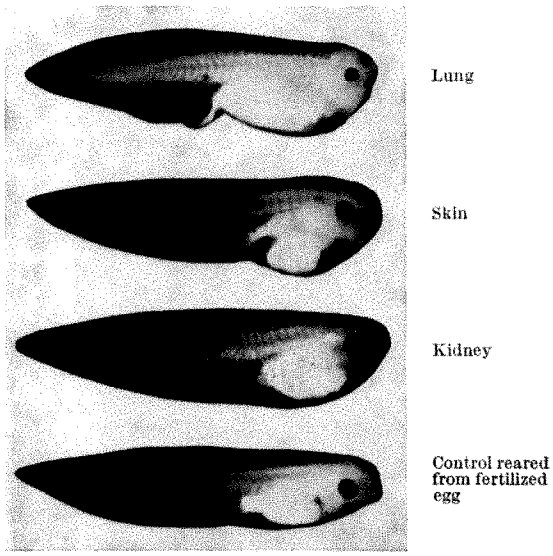

Fig. 4. Swimming tadpoles obtained by serial nuclear transfers from cultures of adult somatic cells. The tadpoles derived from lung, kidney and skin cells were all 1-*nu* diploids (±5), and their nuclei were therefore authenticated products of the transplanted nucleus (×15).

developing from these, and attention has therefore been focused on those embryos which developed as far as or beyond the stage with functional contracting myotomes. The nucleolar number has been determined for sixty-six embryos of this and later developmental stages contained in sixteen serial transfer clones. 71 per cent of these embryos were 1-*nu*, 11 per cent were 2-*nu* and 17 per cent were 0-*nu*. Most of the 0-*nu* embryos were contained in a single clone, and probably arose by loss of the nucleolus-bearing chromosome (or part of it) soon after nuclear transfer. Chromosome preparations were made from thirty-three of the 1-*nu* embryos (Table 2). Thirty-two of these were diploid or near diploid and only one was haploid. Similarly chromosome preparations from 2-*nu* embryos showed two to be tetraploid and therefore products of the transplanted nucleus. From these results it

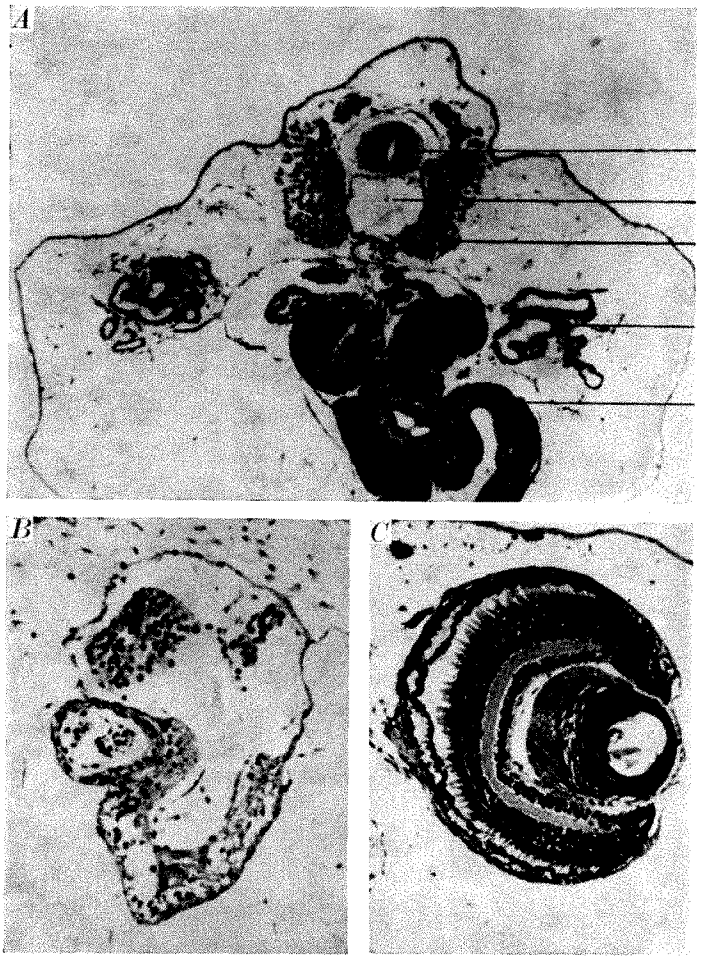

Fig. 5. Transverse sections through a 1-*nu* diploid swimming tadpole obtained by serial nuclear transfer from an adult skin cell. *A*, Dorsal region of mid-body (×150); *B*, heart containing nucleated erythrocytes (×420); *C*, eye (×300).

is clear that the egg nucleus has not participated in most of the nuclear-transplant embryos which reached advanced stages of development. In conclusion, 1-*nu* diploid tadpoles obtained in these experiments constitute a valid test of the developmental capacity of the transplanted nuclei.

Eighty-eight serial-transfer clones were prepared from the nuclei of cell cultures derived from adult organs; 32 per cent contained at least one tadpole which reached the stage of contracting myotomes (about stage 28 of Nieuwkoop and Faber, 1956). Some of these tadpoles were proved to be products of nuclei from adult kidney, lung and skin (Table 2). Furthermore, some tadpoles from each of these sources developed to more advanced stages (stage 41 and beyond[13]) as shown in Fig. 4. They performed frequent normal swimming movements, indicating functionally normal nerves, muscles, and neuromuscular connexions. An extensive and rapid circulation of red blood cells was maintained by a heart contracting regularly, indicating normal cardiac muscle function and erythrocyte differentiation. The nuclear-transplant tadpoles differ from stage 41 tadpoles reared from control fertilized eggs in only one obvious respect, the development of anal and cardiac oedema, a possible cause of their subsequent death. Examination of sections of these tadpoles revealed many different tissues and cell-types of apparently normal construction. Erythrocytes, skeletal and cardiac muscle, pronephros, notochord, nerve cord and complex sensory structures could be identified (Fig. 5). No cell-type could be recognized in tadpoles reared from fertilized eggs which could not be found in the nuclear-transplant tadpoles.

Table 2. VALIDITY OF NUCLEAR TRANSFER EMBRYOS REACHING THE MUSCULAR RESPONSE STAGE

Source of donor nuclei	Number of tadpoles examined	Number of tadpoles known to be derived from only the transplanted nucleus	
		1-*nu* diploids*	2-*nu* tetraploids†
Adult kidney	13	13	—
Adult lung	6	4	2
Adult skin	16	15	—

* 36±5 chromosomes in at least 4 metaphases.

† 72±10 chromosomes in at least 4 metaphases.

The most important conclusions are first that three different somatic tissues of an adult vertebrate contain nuclei which can support the development of tadpoles and must therefore have genes necessary for the formation of many cell-types; and second that no difference has been detected between the development supported by nuclei from adult kidney, lung and skin.

The results reveal very little about the proportion and identity of the cells, within the host tissue, whose nuclei were transplanted successfully. About 25 per cent of nuclear transfers from adult cells gave first-transfer embryos suitable for use as serial transfer donors; of these 32 per cent yielded clones which contained some tadpoles capable of muscular movements. Our two conclusions therefore do not necessarily apply to more than 8 per cent of cells tested. The use of cultures grown from explants in plasma clots largely avoids the specific selection of cells able to stick to the substrate, and the use of nuclei from primary cultures within a week of preparation prevents heavy selection of a minority cell type. Thus our conclusions should apply to typical cells of the host tissues concerned. We are now attempting to extend these experiments to cells which are demonstrably differentiated or determined, using cells derived from adult frog skin.

Neuronal Populations in the Human Brain

THE deterioration of mental function in old age may be due to loss of neurones or decay of their function. Several studies support the former view[1,2] but sample sizes and the number of cases reviewed were small. Accordingly we studied the ventral cochlear nucleus (VCN) because it is well defined and small enough to make accurate counts feasible.

Brains from neurologically normal cases were obtained from autopsies at the Baltimore City Hospitals, the Johns Hopkins Hospital and from the Infectious Disease Hospital in Madras, India. The twenty-three cases ranged from the newborn to 90 years of age. The brain-stem was embedded as a single block in celloidin. Serial sections, 20 μM thick, were taken; every tenth section through the VCN was stained with cresyl violet. The VCN on each section was outlined with India ink, clearly separating it from surrounding structures. Under the 25× objective and with a magnification of 312×, all neuronal nucleoli in each section were counted with a reference grid[3]. Nucleoli or nucleolar fragments less than 1μ in diameter were not counted. Two counts done by different observers were averaged and the sum of the means multiplied by ten. A correction for split nucleoli was used[3].

The neuronal population estimates in the twenty-three cases, arranged by race, sex and age, are shown in Table 1. The figures under "basic count" columns are the totals of the uncorrected neuronal nucleolar counts for each of the two sides. The percentage difference between the two counts is shown in the next column. The "corrected counts" column on the right shows estimated totals adjusted by the nucleolar factor and period. The mean was 48,010 cells with an s.d. of 4,550. The 95 per cent tolerance interval on the central 95 per cent of cases was 37,210–58,810 cells. The percentage difference between the two sides was 0·01–12 per cent with a mean of 4·2 per cent.

Covariance analysis of the regression of count on age suggests no heterogeneity and accordingly the pooled results can be represented by the regression line:

$$y = 47{,}808 + 19{\cdot}77x$$

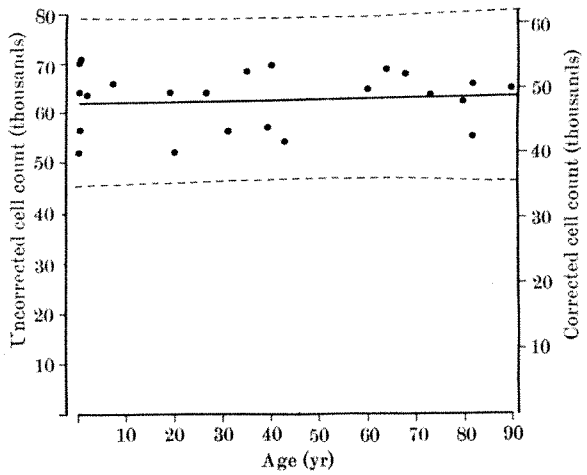

Fig. 1. The relationship between the mean neurone count and age. On the left scale are the uncorrected values and on the right scale are the corrected values. The continuous line is the least squares linear regression line and the interrupted lines are the 95 per cent tolerance limits on the central 95 per cent of the distribution.

where y is the mean of the cell counts in the two nuclei and x is the age in years. The regression line has a positive gradient, but a one-tailed test against the alternative hypothesis that the regression slope is positive gives $t = 0{\cdot}650$, $P = 0{\cdot}2614$. Thus the positive regression slope is not significantly different from zero.

A plot of the mean count against age is shown in Fig. 1 with the fitted regression line through them. Also shown are the 95 per cent tolerance limits on the central 95 per cent of values[4]. Sample estimates of components of variance are:

Within subjects (from comparison of the two sides): $4{\cdot}2 \times 10^6$ counts^2; among subjects: $17{\cdot}7 \times 10^6$ counts^2. Thus more than 80 per cent of the total variance arises from differences among individuals.

In the method used here there are four sources of error. First, outlining structure: the VCN was distinguished by its characteristic medium-sized, plump, ovoid cells, which contrast with the spindle-shaped cells of the dorsal cochlear nucleus; there is little difficulty in separating the VCN from the adjacent pontobulbar body. Second,

Ventral cochlear nucleus: basic counts are the actual neuronal nucleolar counts on each side. Corrected counts are the product of the basic count, the period (10) and the NCF (0·76266).

sampling error: a systematic (periodic) 10 per cent sample gives an accuracy of within 5 per cent of the true count[5]. Third, counting errors occur when sections are poorly stained so that nucleoli are not clearly seen; when sections are too thick, resulting in difficulty in keeping track of the cells counted in a small field; when there is excessive crush cell artefact with nucleoli poorly seen in the densely stained nucleus; when directions are reversed during counting, a portion of a row being missed or recounted; when small neurones are not counted; or when some glial cells are taken for neurones. One author (B. W. K.) took periodic counts checking the accuracy of the two technicians. All counts not clearly wrong were averaged and taken as the number for the nucleus on that slide. Fourth, split cell error, which was corrected approximately[5] by the factor $t/(t+2a)$, where t is the section thickness in microns and a is the thickness of a sector of a nucleolus which presents a cross-section 1 μM in diameter. This formula assumes that the nucleolus is of the same consistency as the remainder of the tissue. There is evidence, however, that it is tougher and may be pushed by the microtome knife into one or the other sections[6]. If this is so, the true neuronal population would lie between the count calculated with, and that without, the nucleolar correction factor. We therefore give the basic count (the sum of the counts on each of the slides), and the corrected count (the product of the total count, period and nucleolar correction factor).

In our group of twenty-three cases, ten had audiometric evaluations. These cases, arranged in order of increasing numbers of neurones in the VCN, showed no clear relationship to the simple hearing tests done. With increasing age the human brain loses both volume and weight. A few studies have suggested that there is a loss of neurones[1,2]. Brody[2] studied blocks of cortex from several areas, in all only about 0·0005 per cent of the total neuronal population of the cerebral cortex. Ellis's[1] estimate of Purkinje cells in the cerebellar cortex was based on a small sample and again inconclusive. Our work suggests that there is no neuronal loss with age in a particular nucleus of the brain stem; but loss may occur elsewhere. Other structures of the brain need to be studied to determine whether the effect of age is uniform. No suggestions have been offered as to why the female brain is lighter than the male. Covariance analysis of the regression of counts in thirteen males and ten females on age shows that the regression slopes are not dissimilar but women have slightly lower mean values. While the difference just attains significance at the 5 per cent level, too much must not be made of this result which may be an artefact of the multiplicity of comparisons. In our series were eleven Caucasians, seven Negroes and five Indians. No significant differences of slope or intercept were found.

Hall[7] found a mean VCN neuronal population, in nine nuclei, of 68,700 (s.d. = 8,000). This mean figure is slightly but not significantly higher than our uncorrected mean count (62,939). His standard deviation was about twice that obtained by us, perhaps because of the smaller sample used in his counts.

Integumental Pigments of the Amphipod, *Jassa*

THE integumental pigments of the isopod Crustacea are ommochromes[1,2], but by contrast the effectively similar colour of the amphipod *Gammarus* is due to carotenoids[3], probably in the form of carotenoproteins. The implication of these findings was that this constitutes a general distinction between these rather closely related orders.

It now seems, however, that *Jassa marmorata* Holmes, also in the suborder Gammaridea, and at least one member of another amphipod suborder have ommochromes as integumental pigments. The possibility was first recognized when the patchy distribution of the dark pigment of *Jassa* was first noticed, that of *Gammarus* being very uniformly distributed over the body. Under the microscope *Jassa* was seen to have a granular pigment, ranging in colour from old gold to dark slate, segregated in the astroid chromatophores characteristic of the Crustacea. The carotenoids of *Gammarus* are very diffusely distributed, not in this special type of cell.

After extracting with methanol the limited amount of carotenoids present in *Jassa* (chiefly, if not entirely, in the viscera, which are not easily removed from such small animals), the integumental pigments were extracted with the usual ommochrome solvents, in particular methanol–HCl and formic acid. Their properties proved very similar to those of isopods[2] and, as in the latter, both ommatin and ommin sub-classes were found to be present.

Fig. 1 shows the absorption spectra, for the range 200–700 nm, of the ommatins extracted by (A) a mixture of 19 parts of methanol and 1 part of concentrated HCl (v/v) and (B) the same mixture diluted with one quarter of its volume of water. The four peaks characteristic of ommochromes[4] are evident. In 5 N HCl the peaks were at 222, 241, 348 and 475 nm, the bathochromic shift of the one in the visible range also being characteristic of ommatins. Also, like xanthommatin, this pigment formed a crimson precipitate on reduction and raising the *p*H to 3–4. The precipitate dissolved in isoamyl alcohol, its absorption spectrum then having peaks at 235, 284, 389 and 486 nm. The oxidized form dialysed through visking tubing, like known ommatins.

After exhaustive extraction of the ommatin, in its yellow oxidized form, mixture A extracted ommin, in its purple reduced form, having absorption peaks at 251, 351 and 514 nm. In 90 per cent formic acid solution the peaks were at 267, 393 and 523 nm. Both ommatin and ommin formed purple to violet "halochromes" in high concentrations of sulphuric acid, in the same conditions as in isopods[2].

Chromatographically, also, using as developer the v/v mixture, formic acid : methanol : concentrated HCl : water (15 : 3 : 1 : 6), the ommatin and ommin behaved like those of isopods. In all significant respects, therefore,

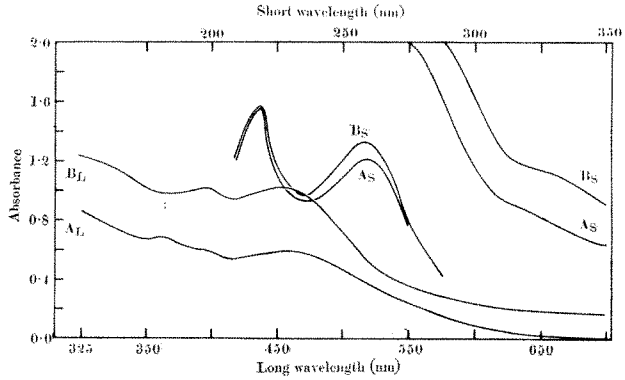

Fig. 1. Absorption peaks of ommatins. S, Short wavelength; L, long wavelength. See text for further explanation.

the ommochromes of *Jassa* are closely related to those of isopods.

As in the isopods, there was some indication that more than one ommatin was present. Thus the material extracted by methanol : HCl : water had its *A*, *B*, *C*, *D* absorption peaks respectively at 219, 257, 393 and 449 nm (Fig. 1), whereas that extracted by undiluted methanol : HCl gave peaks at 218, 259, 360 and 455 nm, with an indication of a second *C* peak at the 393 nm position. On chromatograms there was some indication of two ommatin spots, but overlapping each other as in the isopod material. If there is a second ommatin, similar to the "oniscoid" ommatin[2], it must be a very minor component, quantitatively, for the *D* peak of all extracts from fresh material was in the 450–456 nm range. A lower value, in the range 440 to 450 nm, with a lower peak, was obtained only from moribund material and from material stored for more than 2 days in methanol before extraction, and so may be artefactual.

The absorption spectrum in the various states and solvents, and most other properties examined, imply that the principal ommatin in living *Jassa* is xanthommatin, the most common of biological ommatins. The precipitated, reduced form, however, proved insoluble in phosphate buffer at *p*H 7·0 and the halochrome resembled that of the oniscoid ommatin in its lack of brilliance[2].

An unidentified species of "skeleton-shrimp" belonging to another suborder of amphipods, the Caprellidae, also was found to have integumental ommatin and ommin, arranged in much the same patterns as in *Jassa* and with very similar chemical properties. This group of pigments therefore may be relatively common in Amphipods. They were also found in the same general forms in a tanaid (probably *Tanais cavolini* Milne Edwards), although this is not surprising because the Tanaidacea are generally regarded as closely related to the isopods, but it strengthens the possibility that integumental ommochromes may be characteristic of the Peracarida in general. They have been found in the integument also of decapods and stomatopods[5] and so may be common to the Malacostraca in general. They occur in the eyes of the "Entomostraca" and, altogether, may be as common in Crustacea as in the Insecta.

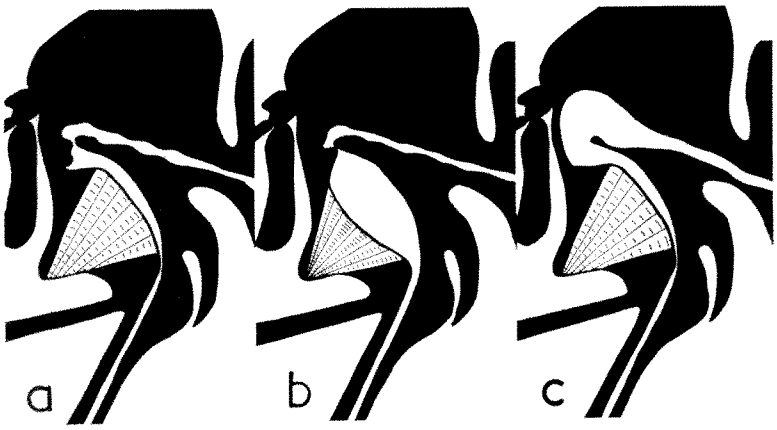

Fig. 1. Diagrammatic sections of tsetse fly head, showing the action of the cibarial pump.

Function of Resilin in Tsetse Fly Feeding Mechanism

Resilin is an elastic structural protein which was discovered by Weis-Fogh in the wing-hinges of locusts[1]. The substance can be identified with certainty only by the use of several tests, by means of which it has been demonstrated in specific areas of cuticle in insects and crustacea[2].

In tsetse flies and other Diptera, food is sucked into the gut by the action of cibarial dilator muscles[3,4]. When the muscles contract, they draw the anterior wall of the cibarial pump away from the more rigid posterior wall, opening the lumen, which fills with food drawn up through the proboscis. Suck-back from the oesophagus is prevented by the dorsal plate, which swings across the oesophageal opening. When the dilator muscles relax, the anterior wall reverts to its resting position and at the same time the dorsal plate swings back, allowing the passage of food into the oesophagus (Fig. 1).

In *Glossina austeni*, the cibarial pump has been operated *in vitro* by depressing the anterior wall with an electromagnetically activated probe[5]. In such experiments the return action of both anterior wall and dorsal plate immediately follows withdrawal of the probe and is independent of muscular activity. The transfer of food from the pump into the oesophagus is therefore a passive process, relying on energy stored in some elastic part of the dilated pump.

The pigmentation of the anterior cibarial wall in tsetse flies has been illustrated by Jobling[3]. Around the dark brown median apodeme there is a more lightly sclerotized area, the rest of the wall being fairly transparent. When the pump is operating, it is the transparent parts which are bent, the peripheral regions of the anterior wall being doubled over[5]. There is little bending at the hinge between the anterior and posterior walls. In the electron microscope the transparent, flexible parts are seen to be unstained and almost completely electron lucent—a characteristic of pure resilin[2]—whereas the posterior wall at the same locus has a dense cuticular appearance (Fig. 2).

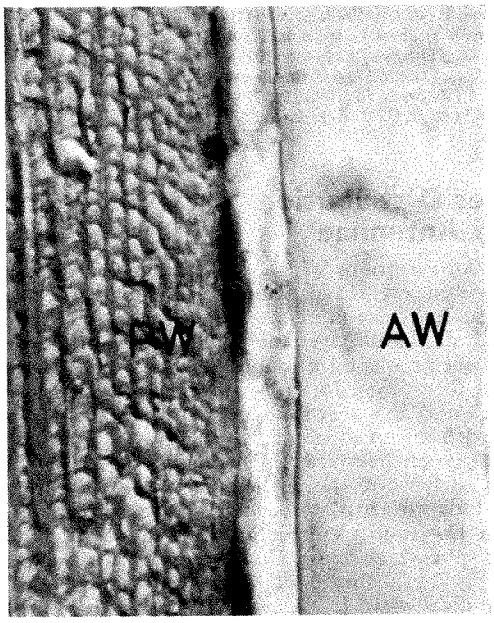

Fig. 2. Electronmicrograph of a section of the anterior (AW) and posterior (PW) cibarial walls of *Glossina austeni*.

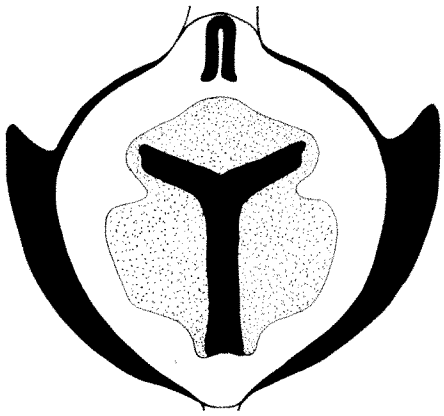

Fig. 3. Diagram to show the topography of resilin (unshaded areas) in the anterior cibarial wall.

The transparent material of the anterior wall fluoresces blue in ultraviolet at *p*H 12 and is stained by aqueous methylene blue solutions at *p*H 7. These are two further characteristics of resilin[2]. Electronmicrographs of the hinge region show that here both anterior and posterior walls are composed of continuous, curved lamellae of cuticle.

The topography of resilin in the anterior cibarial wall of the tsetse fly is illustrated in Fig. 3. Potential energy is stored in this material when it is flexed by the contraction of the dilator muscles. As the muscles relax, the resilin recoils to its undistorted shape, the stored energy being utilized to return the anterior wall and swing back the dorsal plate, so pushing food out of the pump and into the oesophagus.

The structure and function of the cibarial pump in other Diptera (my unpublished observations) and in *Rhodnius prolixus* (ref. 6 and H. C. Bennett-Clark, personal communication) indicate that resilin is a significant structural component of the sucking pump in many different insects.

Species Distribution of New Structures on Fly Antennae

Antennal receptors which mediate various stimuli are concentrated on three segments in higher Diptera[1-3]. The scanning electron microscope (Cambridge Stereoscan) has now disclosed previously undetected structures on the pedicel or second antennal segment of a number of common flies (Figs. 1*a*, *b*). (Specimens were gold coated at 200 Å and the microscope was operated at from 3 to 10 kV with an aperture of 200μ.)

In the green bottle fly, *Phaenicia sericata*, a patch of median surface of the pedicel is usually glabrous and convoluted, with a plate occupying each depression (Fig. 1*c*). In the newly emerged fly, each plate contains a bulbous seta which tapers distally. The plate is bordered posteriorly by a cluster of fine hairs oriented anteriorly into the air stream (Figs. 1*c*, *d*). The number of plaques varies from six to sixteen per antenna, variations occurring between specimens and sometimes between pedicels of the same individual. There are no sexual differences in this species.

Altogether sixteen species of flies belonging to five families, chiefly muscoids, were examined for these plaques. They were found to be maximally developed Calliphoridae (*Calliphora vomitoria*, *Calliphora vicina*, *Cynomyopsis cadaverina*, *Phormia regina*, *Pollenia rudis*, *Phaenicia sericata*, *Phaenicia pallescens*, and *Phaenicia eximia*) and in Sarcophagidae (*Sarcophaga bullata*). They were less numerous or absent in the Muscidae (present in ♂ and ♀ *Musca domestica* in a longitudinal row of two or three plaques; ♂ *Fannia canicularis* had one and ♀♀ had two; missing in both sexes of *Stomoxys calcitrans*; present in both sexes of *Muscina stabulans* in a longitudinal row of four; and present in ♀ *Scatophaga stercoraria* in a transverse row of two). They were absent from a male tachinid parasitoid, *Nemorilla maculosa*, and from both sexes of the non-muscoid *Drosophila melanogaster*.

Intraspecific variation occurs in the number and arrangement of these plaques, but such sibling species as *P. sericata* and *pallescens* are separable. Generic and familial differences are even more distinct: calliphorids have their plaques in a cluster, whereas they are more linear in the sarcophagid and in the muscids which we examined (Fig. 1*e*). The posterior tuft of fine hairs was present in the sarcophagid and in all calliphorids but absent in muscids. A fuller description of species patterns will be published elsewhere.

The tuft of fine hairs is present in old flies but the bulbous setae are lost with age. The latter are solid and tend to fragment before detachment from the socket. A plug often remains in the socket after detachment (Fig. 1*f*). Other antennal setae do not seem to be so fragile and transient. Its rate of loss varies with species. There was a 50 per cent loss among ten-week-old *P. sericata* caged at 23° C, whereas, in *P. pallescens*, the loss was 30 to 80 per cent by the fourth day. In both species loss of these setae was complete or nearly so, after seven weeks. There was no obvious sexual or spatial pattern in the way these setae were lost, and differences could be found between the antennae of the same fly. Collisions of the flies with the interior of the cage may have produced some loss but there were no significant differences after flies were immobilized or had their wings clipped.

The state of these hairs may give a rough indication of a fly's age and this was used to determine the stage in which some of the common flies in the United States survive severe winters. We buried pupae of several species under 4 inches of dry or wet compacted soil and examined the antennae of teneral adults. Antennae of flies emerging from wet soil had a considerable accumulation of particles and could be mistaken for those of old flies. There was, however, only a 0 to 10 per cent loss of bulbous setae in *P. sericata*, and a 0 to 50 per cent loss in *P. pallescens*. The antennae of both species of fly emerging from dry soil retained all bulbous setae and only a few soil particles. The ptilinum undoubtedly protects the delicate antennal structures as it clears an emergence path.

Wild flies were trapped in early spring to determine the stage in which they had overwintered. Cluster flies, *P. rudis*, known to overwinter as adults, were trapped on April 9. Their antennae had no bulbous setae, were covered with debris and had many broken setae. Early spring blow flies, *C. cadaverina* and *C. vomitoria*, trapped during the first two weeks of April had antennae in the same condition. Additional evidence which suggests these flies had hibernated as adults was: (1) most had frayed wings; (2) a number of females had well developed ovaries and when isolated from males in the laboratory laid eggs which produced larvae; and (3) none showed pupal fat balls which are characteristic of recently emerged flies. Because early spring temperatures were sufficiently low to minimize flight activity until the second week of April, it is unlikely that exhaustion of pupal fat balls,

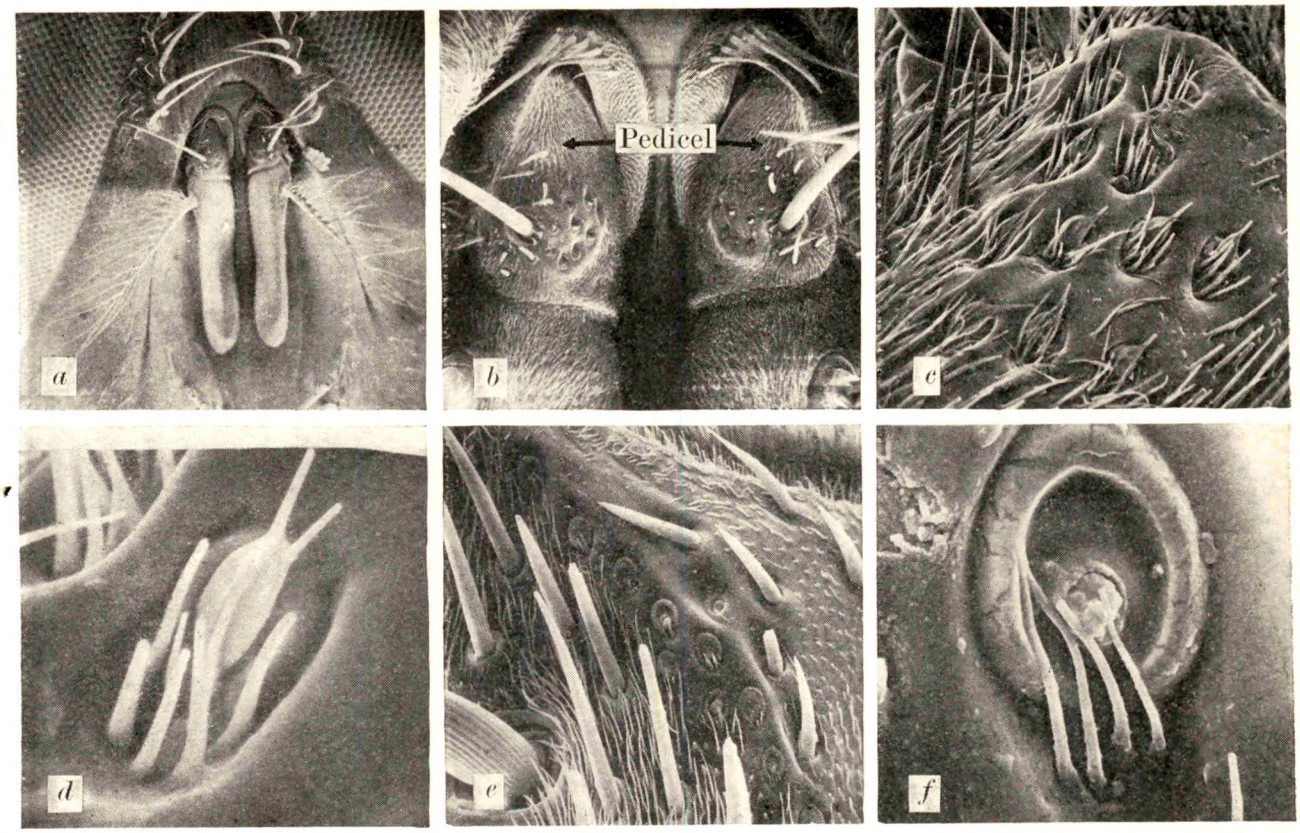

Fig. 1. *a*, Antennae of *P. sericata* (♀, ×32); *b*, same, showing area of pedicel which contains newly described structures (×131); *c*, same, showing pockets of bulbous setae and hairs directed anteriorly (×600); *d*, same, ×2,790 (forked hair is unusual); *e*, more linear arrangement of plaques in *S. bullata* (♀, ×336); *f*, same, showing socket after loss of bulbous seta (×3,330).

ovarian development and insemination, and fraying of the wings could have all taken place in these flies by early April. (Virgin or nulliparous flies may also overwinter. A female *P. regina* collected indoors on January 24, 1970, in Du Page County, Illinois, by Mrs Noreen Ash, had antennae and wings of a hibernating fly with immature ovaries.) The first spring specimens of *P. sericata* taken two weeks later correlated well with teneral adults on the basis of the above criteria. This species must therefore hibernate in a pre-adult stage.

Use of a cuticular structure for age approximations has the advantage that it may be applied to museum specimens. A few of our specimens were more than 20 years old and some retained a high percentage of bulbous setae. Histological and behavioural studies are under way to elucidate the function of these antennal structures.

I thank Ronald G. Wibel for taking the SEM photographs, and Marc Klowden and John Kowalski for technical assistance.

Experiments in Binocular Synchronization

As applied to eye guidance, Helmholtz's classical empirical theory of space perception[1] contains two basic assumptions: first, that direction and location in space are learned by temporal association between visual and tactile experience, and second, that the two eyes are exactly conjugate in their response to visual stimuli. The second assumption is logically necessary because the theory of temporal association permits no time discrepancy between the two eyes in forming visual and tactual associations. If such binocular differences did occur, each eye would "learn" separate directions. We have set out to test this second assumption.

A real-time computer system[2–4] (Fig. 1) was arranged to control and to measure the time intervals between the points of maximum velocity in binocular saccadic eye movements while reading. The movements of each eye were converted to electrical analogues by a binocular transducer fitted to a pair of goggles. The subject read samples of easy and difficult material presented by a motor-driven Teleprompter. To begin with, the computer system was used to control and code recordings of the binocular eye movements on a precision magnetic tape recorder. When the observations were completed, these recordings were reprocessed by computer programming to measure the time differences between the peak velocities of paired binocular saccadic fixations: the primary eye movement signals were differentiated to produce an electrical analogue of their velocity, and the input velocity signals sampled and converted to digital form at 1,000 samples/s. The time measures were accurate to the precision of the sampling rate. Millisecond timing could be achieved because the peak velocity of the eye movement signals could be detected with that precision.

A similar procedure was used in the second experiment to measure time differences in the velocity peaks of vertical eye movements, except that in this experiment the subject watched an oscilloscope target which shifted vertically in position in steps of 2·5 and 5·0 degrees. For this experiment, the photoresistor, binocular, vertical eye-movement transducer was used (Fig. 1). In the first

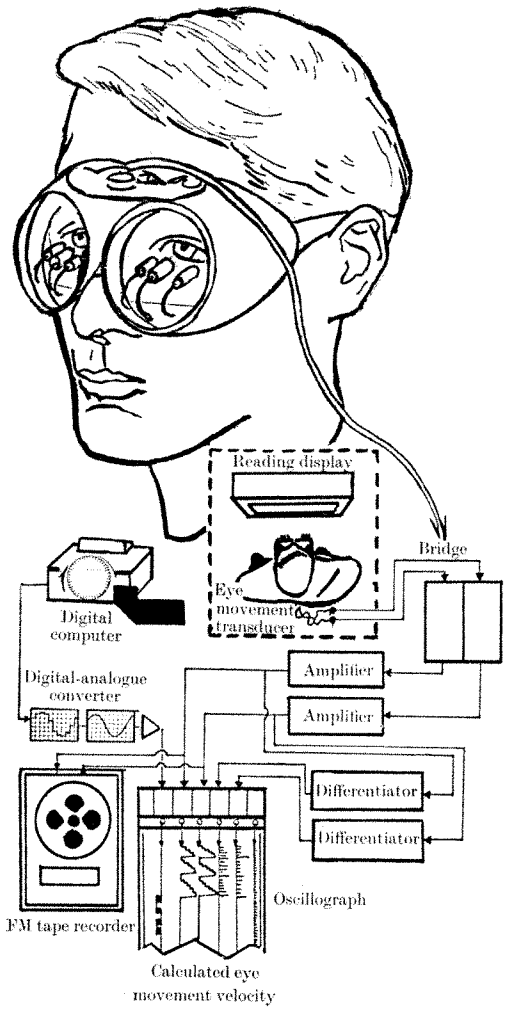

Fig. 1. Vertical photoresistor binocular eye movement transducer and real-time computer system used to measure time differences between the two eyes in visual tracking.

observations, the computer was used to shift the target spot at intervals of 0·35 and 0·70 s and to code the recording of the vertical eye movements. Later, the recorded movements were reprocessed and their velocity derivative obtained and recorded at a rate that would make possible accurate visual measurement of the time differences between the peak velocities of paired binocular saccades.

In the reading experiment, three subjects were tested in a repeated measures experimental design that varied reading difficulty and orientation of the reading display. Three orientations were used: normal, rotated 15 degrees to the right, and rotated 15 degrees to the left. The pattern of the recorded binocular movements are shown in Fig. 2 (top two eye movement traces) with a record of the velocity component of the movements. The computer measured the time differences between the velocity peaks of paired right-eye and left-eye saccades, as illustrated in these velocity records.

The distribution of eye time leads for the three subjects was plotted for the least difficult reading passages (Fig. 3). All three curves have three modal frequencies. Subject 1, unlike the other two subjects, gave a modal right-eye lead at about 5 ms. This subject showed a relatively low

Table 1. TIME LAG IN MILLISECONDS OF THE LEFT AND RIGHT EYES RESPECTIVELY IN RESPONDING TO CHANGES IN TARGET POSITIONS

Subject	Left eye	Right eye	Difference
1	164	161	3 (RE lead)
2	149	171	22
3	208	214	6
4	201	208	7
5	237	248	11

modal lead at 16 ms, and a very high frequency left-eye lead at 1 ms. In contrast subject 2 showed a high frequency left-eye lead at 15 ms and a low left lead mode at 1 ms. Subject 3 showed a somewhat different distribution with the highest modal frequency at 0·0 and nearly equal modal frequencies at 14 and 9 ms. These subject differences in modal

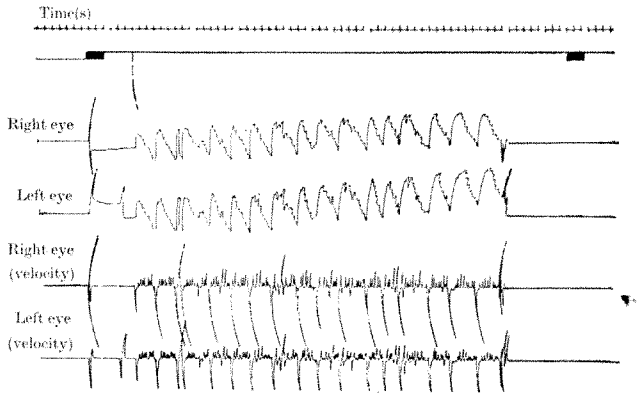

Fig. 2. Records of horizontal binocular eye movements in reading and traces of their velocity. High-precision measurement of binocular differences is achieved by detecting differences between paired velocity measures of the two eyes.

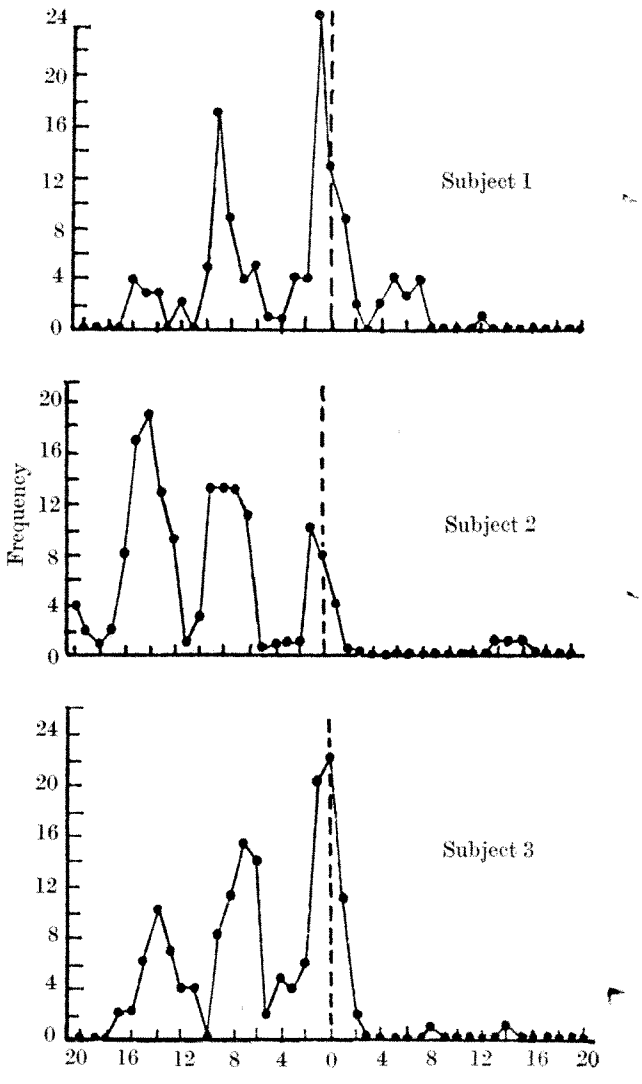

Fig. 3. Distribution of the frequency of right and left eye leads in reading among three subjects.

frequencies at different times were duplicated almost exactly in the other two conditions of difficulty of the reading material and were not changed by its orientation. Statistical tests showed that the differences in frequency of occurrence of the left-eye leads was significant.

The pattern of the vertical eye movements, their velocity characteristics and the difference in position between the right and left eyes are illustrated in Fig. 4. The experimental measurements consisted of time differences between the peak velocities of paired right-eye and left-eye movements, as shown in the lower two traces of the record. Results on five subjects showed that the mean time difference in ms between the two eyes favoured the left eye in tracking the vertical shifts in target position, favoured the left eye in four subjects, and the right eye in one (see Table 1). These differences between eyes were statistically reliable. Over a series of eight practice trials, the mean time between target movement and eye response was reduced significantly from a mean of 220 ms to about 200 ms. With practice, the mean time difference between the right and left eye was significantly increased from approximately 1 ms to about 9 ms.

The results of these experiments on horizontal and vertical binocular movements do not confirm the classical theory of Helmholtz that the two eyes are conjugate in binocular coordination. The finding that the left eye led the right eye in most of the measures of reading substantiates the observations of Hyde[5], who found that "outward" movements of the eye were slower than "inward" movements. The difference was 58 degrees/s (Hyde herself attributed this difference to lack of precision in her technique, and concluded that the eyes are completely conjugate).

The experiment illustrates how real-time computer systems can be used to obtain high-precision measurements in optometry and visual science. These methods, which may be extended to all fields of physiology and psychology, are based on the analogue–digital–analogue computer both as a control element in a behavioural–physiological system and as a high precision clocking and measuring device.

These findings raise questions about the validity of the claims of informational engineers[6] that the dynamics of saccadic movements in vision can be modelled adequately in terms of binary sampling processes related to sensory and neural input, which have an optimal sampling constant or response latency of 0·2 s. The results suggest that binocular visual coordination depends on several levels of continuous eye movement–retinal feedback timing and that these differ significantly for the two eyes and for each pattern of vertical and horizontal eye motion.

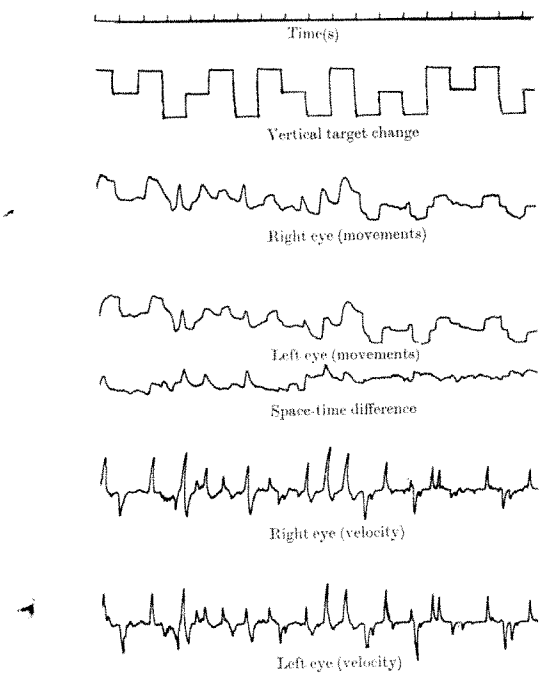

Fig. 4. Records of binocular vertical eye movements in relation to the step-wise vertical shifts in the observed target, with traces of the velocity of the eye movements.

Effect of Blurring on Perception of a Simple Geometric Pattern

FIG. 1 is a modification of the Poggendorff illusion which has been drawn so that it is clearly visible at large distances. When viewed from a distance the central bar is perceived as being more horizontal and wider than it is drawn. This distortion increases as distance from the figure increases so that distortions of 15° can be found in most subjects. (Similar but much less striking distance and size effects have been noted in standard illusion figures[1–5].) The distortion is greater in subjects with poor visual acuity; and it can be increased by artificially increasing the blurring by optical means. The effect does not depend on accommodation, and can also be observed by placing a hair on a fine grating.

Fig. 1. A variant of the Poggendorff illusion.

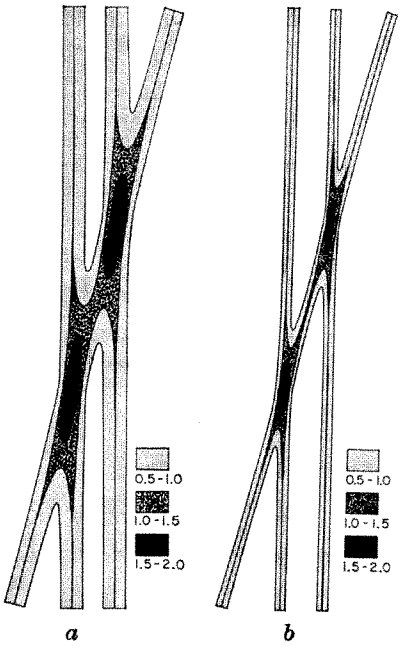

Fig. 2. *a*, The contour map of intensity which results when a line pattern, formed by two parallel lines crossed by a third at a 15° angle, is convolved (blurred) with a Gaussian of unit height. The distance between the parallel lines is twice the half-width of the Gaussian; *b*, the same as *a*, but with the distance between the parallel lines four times the half-width of the Gaussian.

The illusion seems to be caused by the faulty interpretation by the visual system of an image blurred by any combination of optical, motor or neural processes[6]. Here, however, I consider the effects of blurring in foveal vision, for which the blur function has been experimentally determined and may be approximated by a Gaussian whose half-width depends on the pupil size (the half-width is about 1·2 min for a 3·8 mm pupil)[7,8]. The retinal intensity pattern for foveal viewing of a luminous line pattern formed by two parallel lines crossed by a third at a 15° angle, can be computed, and is illustrated for distances between the parallel lines of twice the half-width of the Gaussian (Fig. 2*a*) and four times the half-width (Fig. 2*b*). Away from the points of intersection in Fig. 2, the extent of the blurring is about equal to the visual acuity and we perceive a straight sharp edge (perhaps as a result of neural inhibitive processes in the visual system)[9]. In the vertex of the acute angle, however, there is a plateau of rather slowly changing illumination several times larger than that at the limit of visual acuity. Although it is not easy, it is possible, looking carefully at Fig. 1, to see this blurred region in the vertex of the angle (see ref. 1, Fig. 29). Ordinarily, however, we do not notice these fine details and at large distances we perceive a tilted bar whose boundaries appear to be a "best fit" to a contour of constant intensity (Fig. 2).

In the past, many investigators have proposed that the inability to resolve the vertices of acute angles may lead to their perceptual enlargement, and consequently to many of the geometric illusions (Poggendorff, Zöllner, Hering, Orbison)[1-5,10-13]. Among the many demonstrations which support this hypothesis are the disappearance of the Poggendorff illusion when the ends of the oblique lines meeting the verticals are bent slightly outward near the point of contact[14]; the necessity of acute angles for the Hering illusion[4]; the enhancement of illusions by artificial increases of blurring[10,15]; persistence of illusions in haptic presentation[13]. Although these demonstrations provide evidence that distortions induced by acute angles are important in causing the illusions, many have persuasively argued that other factors must also be involved[1,15-18]. Certainly this is so. Even for such simple patterns as the geometric illusions, it is necessary to consider how information reaching the higher visual system simultaneously through parallel channels, or sequentially because of eye movements: is integrated to yield a single percept. The state of attention of the subject to fine details as well as expectations concerning what the stimulation pattern is will certainly affect this integration.

I have here presented a visual distortion which seems to be caused by the erroneous interpretation of a blurred image. Although only optical blurring has been discussed, "neural blurring" of the visual image at higher levels of the visual system will enhance the optical blurring which is already present at the retinal level. The partial persistence of the geometric illusions in binocular presentation[19] would therefore be expected. Study of the size and distance effect observed here should be useful in determining the rules by which people extract information from visual patterns, and may indicate that the comparatively small regions distorted by blurring in large figures have a large effect on the final percept.

I thank Professor H. C. Longuet-Higgins and Miss Carolyn Cummings for helpful conversations. This investigation was supported by a US Public Health Service postdoctoral fellowship from the National Institute of Mental Health, and a US Public Health Service training grant from the National Institutes of Health. I was a visiting research fellow at the Department of Machine Intelligence and Perception, University of Edinburgh, during 1968–69 when most of this research was done.

Relation of Age and Mongolism to Lateral Preferences in Severely Subnormal Subjects

HILDRETH[1] estimated the incidence of left-handedness in very young children to be about twice as high as in the adult population. This is consistent both with an effect of social training and also with maturation in lateral dominance, but in either case one might expect a subnormal population to show, at least up to a certain age, a greater incidence of left-handedness. Burt[2] and Gordon[3], relying partly on the observations of teachers, both found this; Clausen[4], however, using three objective tests, found no differences between retardate and normal groups aged

8 to 10 years. Severe subnormality, however, has scarcely been investigated; the children examined by Burt and Gordon, and the 46 per cent of Clausen's retardate subjects with IQs above 60, would almost certainly not be so graded. An attempt[5] to differentiate by diagnosis ranked the incidence of left-handedness in groups of subnormal males in the (diminishing) order: "familial", "brain-damaged", "mongols". It therefore seemed worthwhile to investigate lateral preferences in normal and severely subnormal groups, examining separately the effects of age and mongolism.

The greater the number of items used to assess laterality, the more may it appear a matter of degree and we used a wide range of items to make sure of detecting residual left-sided preference. Performance items were used because questionnaires, although they have obvious advantages, are not practicable with the severely subnormal. Also there is evidence[6] of considerable unreliability between questionnaire responses and performance on the same items.

The severely subnormal subjects were thirty-two patients at South Ockendon Hospital divided into four groups of eight (Table 1). The subjects selected were all attending the school, without obvious physical handicap and cooperative. Within these limitations it was not possible to balance the number of males and females, even with a hospital population of more than 1,100, but, because most investigators find a higher prevalence of sinistrality among males (Oldfield[7]), it was felt that the proportion of males must be kept equal between the main groups. Accordingly, there were eleven males in groups 1 and 2 combined, and in groups 3 and 4 combined; the proportion of males in the two normal groups (5 and 6) was made to match this. There were 32 normal subjects (Table 1). The 16 children were selected randomly from a class of 30, with the constraint that 11 must be boys.

The inventory was largely selected from that used by Oldfield, excluding unfamiliar items, dangerous activities, and tasks which could not be initiated by verbal instruction alone. One item added was that of blowing the nose. Thus the items were: writing, drawing, use of scissors, comb, toothbrush, knife without fork, dessert spoon, hammer, screwdriver, broom (upper hand), striking a match, dealing cards, threading a needle, throwing a ball, blowing the nose, kicking a ball and looking through a tube.

The order of presentation was randomized and every item was presented using both hands. If the subject showed uncertainty the score was divided, but this was rare. Three of the subnormal subjects failed to complete some of the items but their results are included because all three completed over half of the inventory. Laterality quotients (LQs) were obtained for each subject, from the commonly used formula:

$$\frac{\Sigma R - \Sigma L}{\Sigma R + \Sigma L} \times 100$$

where R, L are right hand and left hand preference scores respectively. Total right-handedness is then $+100$, and total left-handedness -100.

The frequency distributions of the LQs are shown in Figs. 1 and 2. By inspection the normal group seems the more positively right-handed. Both groups, however, have a clear bimodal distribution, making analysis of variance an inappropriate means of comparison. We decided to use the Kolmogorov–Smirnov test[8] to examine the significance of the largest difference between the cumulative distributions. This showed that the LQs of the normal subjects are higher than those of the subnormal ($P < 0{\cdot}05$, one tailed test); within the normal group there is no significant difference between older and younger subjects, but, within the subnormal group, the LQs of the older subjects are higher ($P < 0{\cdot}05$, one tailed test). Within the subnormal group there is no significant difference between the LQs of mongols and non-mongols. The mean LQ score of the former is 47·1 and of the latter is 25·7; there are, however, only ten males amongst the mongols and twelve amongst the non-mongols, and we also found that males tend to have stronger left-sided preferences than females. Combining groups 1, 2, 3 and 4, the mean male LQ is 29·8 and the mean female LQ is 50·9; combining groups 5 and 6, the figures are, for males and females respectively, 52·0 and 70·0.

No further independent comparisons are possible within the data, but the implication that the greatest

Table 1. DESCRIPTION AND AGE, SEX AND INTELLECTUAL STATUS OF THE FOUR SUB-GROUPS IN THE SEVERELY SUBNORMAL SAMPLE AND THE TWO SUB-GROUPS IN THE NORMAL SAMPLE

Group No.	Description	N	Males	Females	Age range	Mental age range*	Mean IQ
1	Subnormal mongol	8	4	4	12–7 to 18–10	2–9 to 4–0	< 32·0
2	Subnormal non-mongol	8	7	1	10–9 to 17–10	> 2–0 to 6–1†	< 35·4
3	Subnormal mongol	8	6	2	19–4 to 24–0	3–6 to 5–10	< 30·5
4	Subnormal non-mongol	8	5	3	19–5 to 21–6	2–7 to 7–2	< 35·5
5	Normal	16	11	5	14–4 to 15–8	Comprehensive school pupils (mostly selected for grammar school initially)	
6	Normal	16	11	5	18–1 to 24–0	University candidates, first year students and technicians	

$N = 64$. * Based on assessment by Stanford-Binet. † One MA based on Seguin Form Board.

departure from right-handedness arises from the LQs of the younger subnormals is upheld by consideration of the mean LQs. These are for group 1 and 2: 20·2, for groups 3 and 4: 52·7, for group 5: 45·5, and for group 6: 69·6.

The test used does not discriminate between demonstrating increased left-handedness in the sense of showing the presence of a greater number of complete left-handers and of showing a more even spreading of the LQs from the extreme positive end, but inspection of the Figures suggests the latter is nearer to the truth. Because subnormals attending a hospital school probably receive at least as much training as normals in many of the activities investigated, a possible explanation of the results is that lateralization of hand preference in subnormals develops more slowly but not less completely than in normal subjects. Larger samples, however, might show that the difference remains within older subjects, though to a lesser extent.

Further results will be described elsewhere, in particular those relating to the effects of perinatal injury, to performance on individual items of the inventory and to the correlation between performance and questionnaire versions.

We thank Mr J. D. Valentine, of Bedford College, for statistical guidance, Dr S. Glenn, Mr Hasan and others of the Department of Psychology at South Ockendon Hospital who carried out the mental age assessments. Dr Dutton, Superintendent of South Ockendon Hospital, and Mr Colin Vine, of Chingford Senior High School, for the facilities they provided, and the subjects for their co-operation.

Some Parameters of High Output CO_2 Laser Experimental Surgery

FOUR years ago, investigations on carbon dioxide laser surgery were initiated in our laboratory. This laser was relatively inexpensive by comparison with ion lasers, the only other high output continuous wave (CW) lasers with surgical potential. The CO_2 laser could be coupled with beam guides used as manipulators, was flexible, had a high efficiency and provided the continuous wave (CW) power needed for an "optical knife". One disadvantage was, of course, the output of an invisible beam far out in the infrared at 10,600 nm and the consequent expensive infrared optics required. The safety programme for investigative laser surgery has been reported before by our laboratory[1]. Specific hazards for the high output CO_2 laser arise from the reflexions from target areas and from surgical instruments. Our initial surgical experiments with 25 W output (Perkin Elmer CO_2 laser) were done on metastatic melanoma of man. Non-specific thermal coagulation necrosis developed after laser surgery. There was no local dissemination of tissue fragments from the CO_2 laser.

Recently, an American Optical 50–300 W CO_2 laser furnished with a flexible beam manipulator and with an endoscope and gastroscope has become available for investigative laser surgical research[2]. This led to renewed interest in the possibility of using CO_2 lasers, especially for so-called bloodless surgery in highly vascularized areas. Sterile coverings of the manipulator head can be used to ensure sterility during the operation. Animal experiments with this laser at 30 W output included the production of partial and complete heart block of dogs by Naprstek and Rockwell[4]. In these experiments the laser was used for the initial skin incision, the thoracotomy and entry into the endocardium. No other types of instruments were used for haemostasis. Precise lesions could be produced in the conductive bundle as observed by the monitoring instruments. In these investigations, the precision and relative bloodlessness of the laser were evident.

Detailed experiments were done by Rockwell and Hishimoto on the CO_2 laser parameters of the liver surgery of rats, and by Siler, Naprstek and Hoefer on surgery of the liver of dogs. These experiments[7] quantified the laser reaction in tissue as regards heat retransmission, depth of incision and focused power density; they also collected data on histology, histochemistry and liver function. These data will be reported later. Such research in liver surgery is necessary for there has been increased frequency of liver damage from the sudden pressure of seat belts in deceleration in automobile accidents. In these preliminary studies the CO_2 laser was found to be superior to the current instrument of preference, the high frequency electro-surgical knife: haemostasis from capillary bleeding was controlled well. Bleeding from moderate and large vessels, however, was not controlled. Experiments are now under way with special thrombin and gelfoam packs combined with laser "welding" techniques to close bleeding points. At present, for extensive liver surgery in the dog, 125 W output is preferred. Similar results in liver surgery with the CO_2 laser were found by Mullins, Jennings and McClusky[5] and by Goodale, Okada, Gonzales, Borner, Edlich and Wangensteen[6]. Goodale has also used the CO_2 laser in the treatment of a stress ulcer. These investigators have used this laser also in treatment of experimental gastric haemorrhage in dogs. Stellar (personal communication) has used the CO_2 laser for neurosurgery in animals and for excision of third degree burns in the pig. Hobe'ika in our laboratory has used the CO_2 laser with the endoscope for surgery of the larynx in dogs. Miller, Winston and Wilson in our laboratory are also using the high output CO_2 laser for cutting and welding bones in the rabbit and dog.

Recently, another type of CO_2 laser was used. This was a pulsed high frequency laser (249 pulses/s) developed by Douglas Linn (Linn, D., personal communication) of Lasers Systems, Inc. Initial experiments were done on liver, kidney and bones of the dog. With outputs of 80 W, the cutting of tissues was excellent but plumes of blood were observed and active haemorrhage in tissue developed. To retain the rapid and precise surgery of these high output instruments and to reduce bleeding, some of the output parameters of these lasers are being varied.

The American Optical high output CO_2 laser system at 35 W has been used to excise two malignancies in man. This was done primarily because the area of the cancer was highly vascularized in these patients. One patient had a 2·0 cm basal cell epithelioma of the posterior aspect of the neck recurrent after previous electrosurgery and X-ray radiation. This was in an area where extensive actinic changes with telangiectasia had developed. This area bled freely. The CO_2 laser was used with local anaesthesia to excise an oval piece of tissue. No other instruments were used. There was only minimal haemorrhage. The wound was closed with interrupted black silk sutures reinforced with Steri-Strips. Detailed biopsy studies showed adequate excision of the epithelioma in all planes with only a narrow rim of coagulation necrosis which did not extend into the invasive tumour cords. When the sutures were removed at 7 days, some broadening of the scar was seen but the

lesion had healed. The area was soft and has remained free of cancer during the brief observation period of 8 months.

The second patient had 2·5 cm lobulated angiosarcoma of one finger. Under local anaesthesia and tourniquet, three separate sections were removed with the scalpel, the CO_2 laser and the high frequency electrosurgical unit respectively. Biopsy sections from the scalpel and the laser were adequate for detailed histological studies, whereas the sections from the high frequency electrosurgery instrument showed complete charring of the entire tissue mass. With the release of the tourniquet, extensive bleeding occurred only in the scalpel control area and three blood vessels had to be ligated. There was a small recurrent nodule 3 weeks after surgery only in the area of the scalpel. This was treated effectively with local X-ray irradiation to the nodule only. Follow up studies after only 9 months showed smooth, soft scarring, but no evidence as yet of any local recurrences.

With planned safety programmes, the high output CO_2 laser can be used in investigative laser studies. Increased flexibility is necessary for continued, surgical research with this laser. The high output CO_2 laser then is another significant development for current investigative surgery.

Chlorobium Vesicles: the Photosynthetic Organelles of Green Bacteria

Among photosynthetic organisms, green and purple bacteria are distinguished by their failure to evolve oxygen, a reflexion of their inability to use water as a photosynthetic electron donor. Although the mechanism of photosynthesis is grossly similar in these two groups of bacteria, its machinery is not. The photopigment systems of green and purple bacteria are group-specific; and their intracellular locations differ[1,2].

Electron micrographs of parts of the cortical area of each type of cell are shown in Fig. 1, and diagrammatic interpretations of the topological relationships between the cortical cell structures in Fig. 2. The cell membrane of purple bacteria is topologically very complex; numerous intrusions, with the form of vesicles, lamellae or tubules, penetrate deeply into the cytoplasmic region. The photopigments are incorporated into this complex unit membrane system[2,3]. In green bacteria, infolding of the cell membrane is less extensive. It occurs at only a few points to form structures similar to the mesosomes found in many groups of non-photosynthetic bacteria. Underlying the cell membrane (but not connected with it) is a cortical layer of oblong vesicles known as chlorobium vesicles, with which the photopigment system is associated[3–6]. Each vesicle is approximately 35 by 120 nm, and is bounded by a non-unit membrane only 2–3 nm thick.

Certain acyl lipids, which include mono- and digalactosyl diglycerides, are specifically associated with the eukaryotic photosynthetic apparatus[7]. These two galactolipids are present in the cells of blue-green algae[8], but have not been detected in the cells or photosynthetic membrane systems of purple bacteria, which contain predominantly phospholipids[8,9]. The cells of green bacteria, however, contain large amounts of glycolipids in addition to phospholipids[10,11]. The glycolipids of *Chloropseudomonas ethylica* have been characterized chemically[11]. "Glycolipid I" is a monogalactosyl diglyceride, and therefore belongs to one of the classes of glycolipids associated with the photosynthetic apparatus of oxygen-evolving photosynthetic organisms. "Glycolipid II", which contains galactose, rhamnose and a third unidentified sugar, has not been found in any other biological group. These analyses were performed on whole cells, and therefore do not reveal the specific intracellular locations of glycolipids I and II.

After glutaraldehyde fixation of crude, cell-free extracts (essential to stabilize the chlorobium vesicles), we have succeeded in fractionating the particulate components of green bacteria by a combination of differential centrifugation and sucrose gradient electrophoresis[12,13]. The preparations of vesicles and membrane fragments so obtained

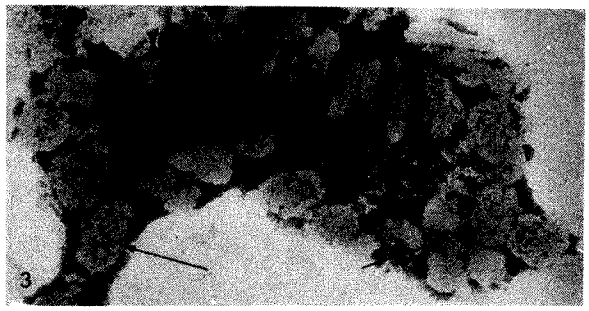

Fig. 3. Electron micrograph of the purified vesicle fraction of *C. thiosulfatophilum* 6130, negatively stained with phosphotungstate. ×80,000.

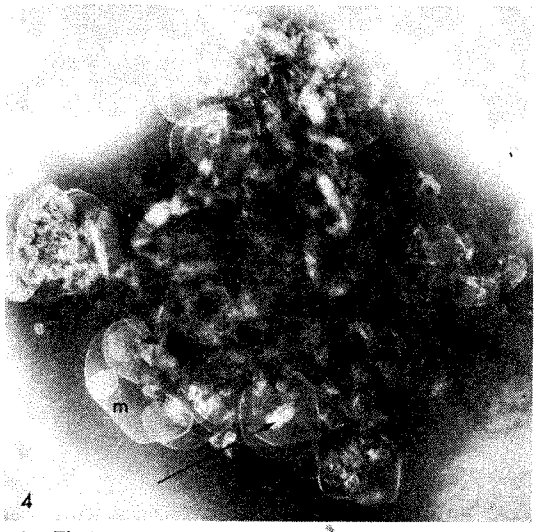

Fig. 4. Electron micrograph of the purified membrane fraction of *C. thiosulfatophilum* 6130, negatively stained with phosphotungstate. ×48,000. The preparation consists predominantly of flattened membranes, probably derived from mesomal intrusions.

seem from their appearance in the electron microscope (Figs. 3 and 4) to be relatively pure. Table 1 presents analytical data on these fractions, isolated from a strain of *Chlorobium thiosulfatophilum*. The purified vesicle fraction is extremely rich in chlorophyll; its specific chlorophyll content is 9 times that of the initial crude cell-free extract. Although the membrane fraction contains some chlorophyll, its specific chlorophyll content is less than 10 per cent of that of the vesicle fraction, and can be reasonably attributed to contamination with vesicles or comminuted fragments derived from them. Particulate succinic and malic dehydrogenase activities are found almost exclusively in the membrane fraction; these two enzymatic activities are characteristically associated with the cytoplasmic membrane system in other bacteria.

Table 1 also shows the phosphate and carbohydrate contents of the lipids extracted from vesicles and membranes. Both glycolipids and phospholipids are present in each fraction; but glycolipid predominates in the vesicles, and phospholipid in the membranes. The glycolipids of the vesicle and membrane fractions were characterized by the methods of Constantopoulos and Bloch[11]. Fig. 5 shows that one specific glycolipid is associated with each fraction. The glycolipid in the vesicle fraction corresponds to "glycolipid I" of Constantopoulos and Bloch[11], and the glycolipid in the membrane fraction to "glycolipid II". We have found the same glycolipids, with the same localization, in vesicle and membrane fractions of another strain of *C. thiosulfatophilum*, and of a strain of *C. limicola*. "Glycolipid I" and "glycolipid II" are therefore probably characteristic cell constituents of all green bacteria.

§ Assay method and unit[17]. About 30 per cent of the initial activity of this enzyme survives glutaraldehyde treatment of crude extracts.

‖ Total lipids extracted from lyophilized preparations with chloroform–methanol (1 : 1) for several hours. Analytical methods have been described in refs. 12 and 13.

The identification of "glycolipid I" as a monogalactosyl diglyceride[11], coupled with the present findings, shows that chlorobium vesicles contain one of the two classes of galactolipids associated with the photosynthetic apparatus of oxygen-producing photosynthetic organisms. This is the only galactolipid present in the photosynthetic apparatus of green bacteria. "Glycolipid II", which has not been detected in other photosynthetic organisms, is a constituent of the unit membrane system of green bacteria, and therefore has the same intracellular location as the glycolipids which occur in many non-photosynthetic bacteria[18,19].

This work confirms the hypothesis that chlorobium vesicles are functionally specialized organelles, which house the machinery of photosynthesis in green bacteria. The absence of unit membranes is the most remarkable property of these organelles. In other groups of photosynthetic procaryotes and in the chloroplasts of eucaryotes, the lipid-soluble photopigments and the associated machinery of photosynthetic electron transport are invariably built into unit membrane systems ("thylacoids"). Although the chlorobium vesicle is to some extent a functional analogue of the chloroplast, the differences between the two are so great that they cannot be construed as homologous. The green bacteria seem to be an isolated and highly specialized group of photosynthetic organisms, remote from the major line of cellular evolution among procaryotes which led to the emergence of organisms capable of using water as a photosynthetic electron donor (exemplified by the contemporary blue-green algae), and eventually to the implantation of this mode of photosynthesis among eukaryotes.

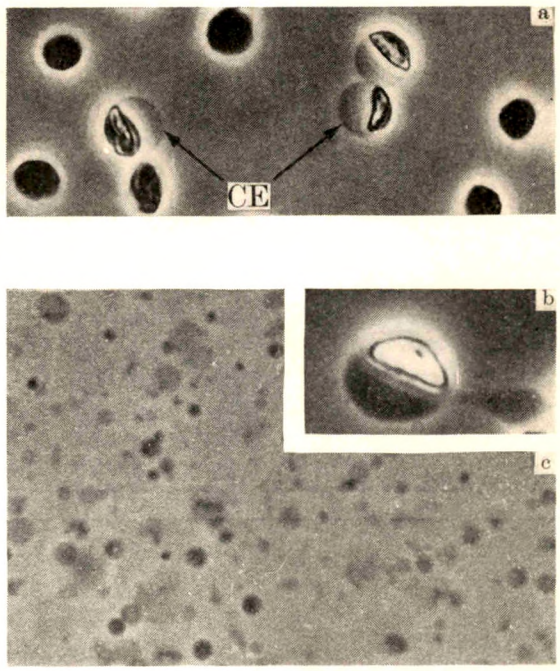

Fig. 1. Phase contrast micrographs of suspensions containing chloroplasts (*a* and *b*) and chloroplast envelope membranes (*c*). In *a* the chloroplast envelopes (CE) of the swollen chloroplasts are seen as greyish halos: the other chloroplasts are devoid of envelopes. The pinching off of a portion of the envelope is shown in *b*. Photography as previously described[17] except that Kodak 'Tri-X Pan' (400 ASA) film was used. (*a*, ×800; *b*, ×1,500; *c*, ×1,430.)

Isolation of Chloroplast Envelope Membranes

LITTLE is known of the nature of the chloroplast envelope: investigations have been concerned chiefly with its role in granal membrane development (for review see ref. 1) and in the transport of metabolites between the chloroplast and the cytoplasm[2–13]. The lack of knowledge of the physical and chemical properties of the plastid envelope limits our understanding of its function in photosynthesizing chloroplasts and of its precise role in plastid development. As relatively few methods are available for the investigation of the envelope *in vivo*, it seemed valuable to devise a method for the isolation of envelope membranes from other chloroplast components and then to study the properties of the isolated envelopes. In this paper we give details of a protocol for the isolation of a membrane fraction containing substantially pure chloroplast envelope membranes.

Vicia faba L. (var. Dwarf White Fan) plants were grown in controlled environment conditions as described previously[14]. The plants (17–21 days old) were placed in the dark for 66–72 h before harvesting, and chloroplasts were isolated from 30–40 g leaf tissue as previously described[14]. The grinding medium was 53 mM Na_2HPO_4 – KH_2PO_4 (*p*H 7·3) containing 0·5 M D(−)-sorbitol, 10 mM $MgCl_2$ and 10 mM EDTA (disodium salt). The chloroplast suspension, which contained 50 per cent–70 per cent intact plastids as judged by phase contrast microscopy, was the starting material for the chloroplast envelope isolation. These suspensions (0·3–0·4 mg chlorophyll/ml.) showed succinic dehydrogenase activity, indicating the presence of mitochondria, and the bacterial count was about 25,000 colonies/ml. Because both mitochondria and bacteria would be a potential source of membrane contamination, the chloroplasts were centrifuged again at 500*g* for 15 min through a 4 cm layer of isolation medium in which the density was increased by substituting 0·4 M sucrose for 0·5 M sorbitol. This centrifugation reduced both the mitochondrial and the bacterial contamination by 60 per cent. The supernatant was carefully removed by surface suction.

Each washed chloroplast pellet was resuspended in 10 ml. grinding medium from which the sorbitol had been omitted, and incubated at 0° C for 10 min. The suspensions were homogenized in a Ten-Broek ground-glass homogenizer by raising and lowering the plunger rapidly three times. The homogenized suspension was diluted with 20 ml. of incubation medium, and centrifuged at 3,000*g* for 10 min. Floating material was removed and the supernatant decanted and recentrifuged at 20,000*g* for 30 min. The pellet from this spin contained the chloroplast envelope membranes.

At each stage during the isolation procedure the suspensions were observed by phase contrast microscopy. Initially the intact chloroplasts were opaque and shining in appearance, but after incubation the suspensions contained many chloroplasts with greyish halos (Fig. 1*a*). In each of these chloroplasts the lamellae system was excentric within the greyish balloon-like structure. This image was interpreted as the side view of an intact chloroplast in which the envelope had become greatly distended. Occasionally the greyish structure was pinched off (Fig. 1*b*) free of lamellae and resembled a red blood cell ghost. These ghosts were assumed to be derived from the chloroplast envelopes, and increased in number after homogenization. The later stages in the procedure were designed for the collection of the ghosts free from lamellae membranes and the final envelope fraction contained numerous ghosts of varying sizes (Fig. 1*c*). When examined in the electron microscope, the pellet of the membrane fraction (20,000*g*) showed a gradation (Fig. 2). Near the top (*A*) the pellet consisted of an almost pure membrane fraction of double-membrane bound vesicles. These vesicles ranged in diameter from 0·3 μm to 1·0 μm

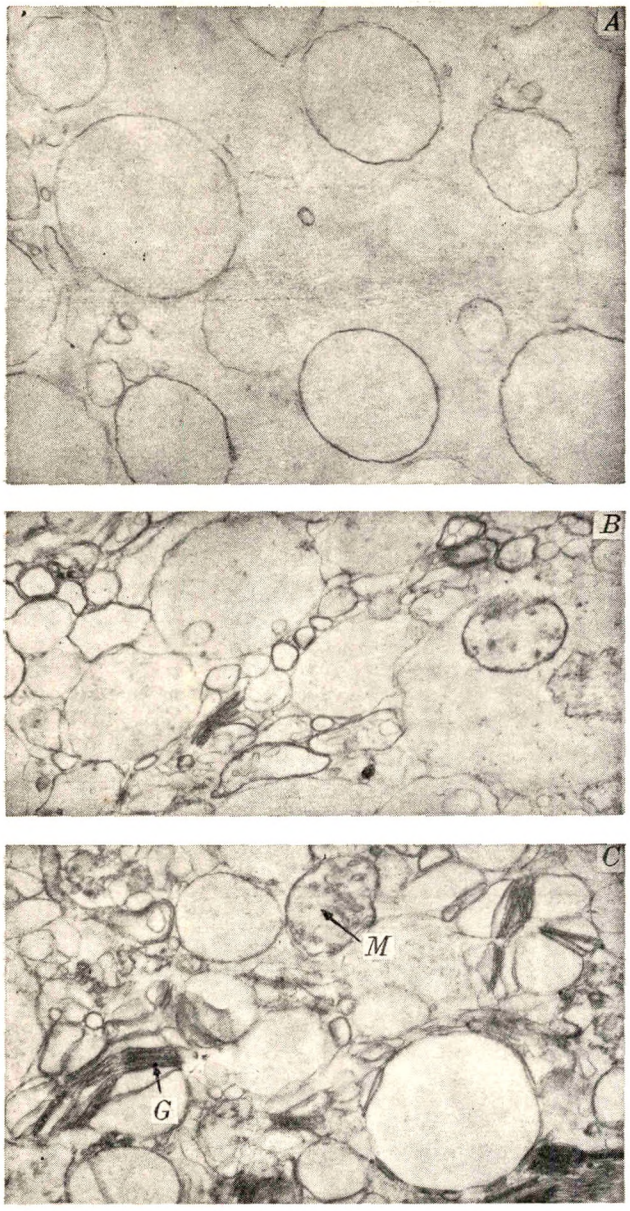

Fig. 2. Electronmicrographs of thin sections from the top (*A*), middle (*B*) and bottom (*C*) of a pellet of the chloroplast envelope fraction. The pellet was fixed with 2·5 per cent glutaraldehyde and post-fixed in 1 per cent osmium. Fixation and postfixation were each for 30 min at room temperature and the fixatives were phosphate buffered at *p*H 7·0. The pellets were dehydrated in an acetone series and embedded in 'Araldite'. The sections on uncoated grids were stained with lead citrate[20]. *M*, Mitochondria; *G*, granal membrane stacks. (*A*, ×31,875; *B*, ×11,250; *C*, 15,000.)

and have the appearance to be expected of contracted isolated chloroplast envelopes. Towards the middle, the pellet became much more mixed and contained vesicles bounded by double and single membranes, recognizable mitochondria (*M*), and granal membrane stacks (*G*). Some of these vesicles probably come from membranes detached from the chloroplast lamellae during incubation and homogenization. At the bottom of the pellet (*C*) an occasional entire chloroplast stripped of its outer envelope was found.

The lamellae membranes contain chlorophyll which may be assumed to be absent from the chloroplast envelope[15]. To assess the degree of contamination of the membrane fraction with lamellae membranes, chlorophyll and protein composition was determined for several preparations (Table 1). The protein : chlorophyll ratio for lamellae from *Vicia faba* chloroplasts is 1 : 1 (ref. 16 and R. O. M., unpublished results) and values greater than this indicate the presence of other protein-containing membranes which do not contain chlorophyll. Despite the fact that small changes in the chlorophyll values give relatively large changes in the protein : chlorophyll ratio (see experiments 2 and 3) the calculated per cent contamination by lamellae membranes is consistent between experiments. It is clear that only 8 per cent – 16 per cent of the membrane protein in the chloroplast envelope fraction is lamellar in origin. Similar calculations for mitochondrial protein, based on estimates of succinate dehydrogenase activity, give values of a maximum of 1 per cent–3 per cent mitochondrial protein in the final membrane preparation.

Table 1. CHLOROPHYLL AND PROTEIN COMPOSITION OF SEVERAL PREPARATIONS

Experiment	Age (day)	Protein (A) (μg/ml.)	Chlorophyll (B) (μg/ml.)	Ratio A : B	Lamellar protein
1 (4)	18	47·7	7·8	6·2	16 per cent
2 (2)	19	38·5	4·7	8·2	12 per cent
3 (4)	19	42·5	3·4	12·5	8 per cent
4 (6)	21	21·8	2·9	7·7	13 per cent

Composition of a fraction containing chloroplast envelopes prepared as described in the text. The number of replicas for each experiment are shown in parentheses. Protein determined on an 80 per cent acetone precipitate according to Lowry *et al.*[18]; chlorophyll determined by the method of Arnon[19]. Lamellar protein is expressed as a per cent of the total protein and assumes protein : chlorophyll ratio of 1 : 1 in the lamellae membranes (ref. 16 and R. O. M., unpublished).

Table 2. COMPOSITION OF FRACTIONS CONTAINING CHLOROPLAST ENVELOPE MEMBRANES

Experiment	μg/100 g leaves Protein	μg/100 g leaves Chlorophyll	Non-lamellar protein	Per cent intact chloroplasts in starting material
1	450	46	404	40–50
2*	293	86	207	15–25
1	130	25	105	5–10

The percentage of intact chloroplasts is a visual estimate of preparations viewed by phase contrast microscopy.
* Incubation at 10° C. Postincubation centrifugation 1,000*g* for 15 min.

The difference between the total protein and the lamellae protein in this membrane fraction gives a good quantitative estimate of the chloroplast envelope material present. The greater the percentage of intact plastids in the original chloroplast suspension, the greater should be the proportion of envelope protein in the final membrane fraction. The data in Table 2 shows that there is a direct relationship between the percentage intact plastids in the original chloroplast suspension and the non-lamellar protein in these membrane fractions isolated from it.

The appearance of the membrane fraction by phase contrast microscopy and in the electron microscope and the demonstration that it is enriched with membrane protein not associated with chlorophyll suggests that it is suitable for further investigation of the chemical and enzymological properties of the chloroplast envelope membrane.

We thank Dr. W. W. Thomson for the electron micrographs shown in Fig. 2.

Light Compensation Points and Photorespiration

SOME results of an investigation into light compensation points of photosynthesizing leaves are relevant to arguments about the occurrence or absence of photorespiration in illuminated leaves of species which do not release carbon dioxide into carbon dioxide-free air, and which have a carbon dioxide compensation point (Γ) close to zero[1–3].

At the light compensation point equivalent amounts of carbon dioxide are evolved and fixed photosynthetically within leaves, and because increases in temperature cause greater increases in the rates of processes which produce carbon dioxide than in rates of photosynthesis, light compensation points increase with temperature (Fig. 1). The points shown are the means of values obtained with four leaves from each species; temperatures stated are measured leaf temperatures. Light was supplied by water-cooled incandescent lamps suspended at variable heights above a constant temperature leaf chamber; intensities were measured with a barrier cell held in a very flat frame and calibrated with a megatron light meter; the cell could be moved to immediately above the leaf surface inside the chamber. The light compensation point was taken as the intensity at which the concentration of carbon dioxide in the closed circuit was maintained at 310 p.p.m. for 30 min.

With one notable exception the light compensation point was apparently most closely related to leaf thickness and the amount of non-chlorophyllous tissue in the leaves; this is best illustrated by the sun and shade leaves of *Impatiens parviflora* (Balsam) and of copper beech. In the latter, however, the sun leaves were reddish-brown and the shade leaves a dull green. There was a similar relation between the light compensation points of sun and shade leaves in *Rhododendron*.

The somewhat fibrous leaf of sugar cane (a zero-Γ plant) was clearly exceptional but the other zero-Γ plant, maize, did not have this exceptionally low light compensation point and differed very much from sugar cane in its temperature response. Both plants were grown in a glasshouse; it was not possible to distinguish between sun and shade leaves in these plants. On many days during the growth of these plants light intensities reached 80,000 lux. Day temperatures were usually hotter than 25° C and often reached 37° C.

It could be argued that in sugar cane leaves the rate of evolution of carbon dioxide in the light was as low as in shade leaves, but this is not so for maize with a light compensation point of 2,300 lux at 35° C—its optimum temperature for photosynthetic performance. As reported earlier[4], maize does not establish zero-Γ at temperatures hotter than 30° C and the minimum light intensity to reach zero-Γ at 30° C is about 5,000 lux. In spite of its low light compensation point the same is true of sugar cane; its light requirement for establishing zero-Γ at 30° C was higher than that of maize. The dark respiration rate of sugar cane was 0·8 mg of CO_2 dm^{-2} h^{-1} at 25° C and 1·6 mg of CO_2 dm^{-2} h^{-1} at 35° C; for maize the values were 1·6 and 3·4 mg of CO_2 dm^{-2} h^{-1} respectively. Anatomical differences between the two species relate to the distribution of chlorenchyma, but it is difficult to see a connexion between these and the very different light compensation points.

These results support the view that in illuminated maize leaves (and perhaps sugar cane too) carbon dioxide is evolved but not released into carbon dioxide-free air, because of an effective carboxylation mechanism which is probably not restricted to cells containing distinct chloroplasts[5,6]. This does not preclude the possibility that at intensities above the light compensation point the evolution of carbon dioxide is progressively inhibited, but there is no good evidence for this view.

CO_2 Assimilation by Chloroplasts illuminated on Filter Paper

CHLOROPLAST suspensions from *Spinacea oleracea* or *Pisum sativum* assimilate CO_2 in the light at rates comparable with those observed with intact leaves[1–3]. With most preparations the major photosynthetic products are phosphoglyceric acid (PGA) and dihydroxyacetone phosphate (DHAP)[2,4,5]. Although the synthesis of these compounds is consistent with the operation of the photosynthetic carbon reduction (PCR) cycle[6] in the isolated plastids it is still not clear why these particular intermediates accumulate. It has been shown[5] that the outer membranes of the chloroplasts are permeable to both PGA and DHAP. Thus a large proportion of the carbon fixed into these compounds may diffuse into the external medium. The amount of carbon lost from the chloroplasts will presumably depend on the ratio of the volume of external medium to that of the aqueous phase of the chloroplasts. For chloroplast suspensions containing 100 μg chlorophyll per ml. this

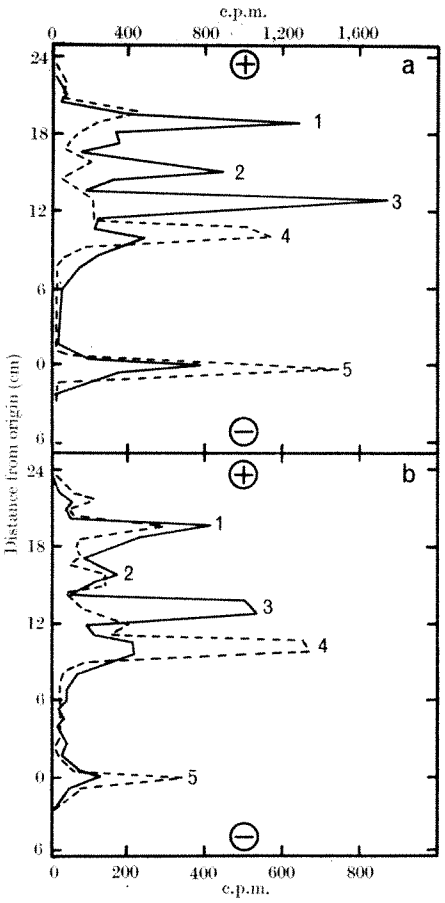

Fig. 1. Distribution of radioactivity into photosynthetic products after 20 min illumination of (*a*) spinach chloroplasts and (*b*) pea chloroplasts in suspension (———) or on filter paper disks (- - - -). Ethanol extracts were resolved using high voltage paper electrophoresis in pyridine–acetic acid–water. The principal peaks of radioactivity correspond to (1) phosphoglyceric acid, (2) sugar diphosphates, (3) dihydroxyacetone phosphate, (4) hexose monophosphates, (5) glycine plus serine plus alanine.

ratio would be over 100 : 1, contrasting markedly with the fluid environment of the chloroplasts *in vivo*, where the ratio of the volume of non-chloroplastic cytoplasm to that of the chloroplasts is usually less than one. It seemed possible, therefore, that more of the PGA and DHAP formed might be metabolized further if the volume of medium in the experimental sample was reduced to a minimum by layering the chloroplasts on filter paper.

Chloroplasts prepared by conventional techniques[7] from leaves of spinach (*Spinacea oleracea*) or peas (*Pisum sativum*) were resuspended in a medium containing 0·33 M sorbitol, 0·001 M $MnCl_2$, 0·001 M $MgCl_2$, 0·002 M versene, in 0·05 M HEPES (N-2-hydroxyethyl-N′-2 ethane sulphonic acid) buffer (*p*H 7·5). Chloroplasts in suspension, equivalent to 100 μg chlorophyll, were spread on disks of Whatman number 42 filter paper (diameter 2 cm) placed on a coarse glass sinter connected to a filter pump. Suction was maintained until all visible moisture had been removed. The disks were illuminated in 'Perspex' chambers of 5 or 10 ml. volume at 60,000 lx and 25° C. Radioactive $^{14}CO_2$ (0·5 per cent by volume) was generated in the chambers by injecting $Na_2{}^{14}CO_3$ into central wells containing lactic acid. The chloroplasts were inactivated and extracted by plunging the paper disks into hot 80 per cent ethanol. Alternatively chloroplasts equivalent to 100 μg chlorophyll were illuminated in 300 μl. medium containing 3·3 mM $Na_2{}^{14}CO_3$ in glass centrifuge tubes sealed with Subaseals[8] at 60,000 lx and 25° C.

In the first type of experiment the chloroplasts were assimilating gaseous CO_2, whereas in the second, carbon was available as bicarbonate ions. This made it difficult to compare the effective CO_2 concentrations of the two systems. The amount of carbon fixed, however, was not increased if the amount of carbon introduced into the experimental system was increased, so it was concluded that the chloroplasts were saturated with CO_2.

The time course of $^{14}CO_2$ assimilation by chloroplasts illuminated on filter paper supports was basically similar to that reported for chloroplasts illuminated in suspensions[1]. A lag period of about 3 min was followed by a period of rapid CO_2 fixation which lasted about 10 min. The rate of fixation then decreased significantly. The maximum rate of fixation extrapolated from time course experiments was equivalent to about 15 μmoles CO_2 assimilated per mg chlorophyll per hour. This compared with rates of about 20 μmoles CO_2 per mg chlorophyll per hour for chloroplasts illuminated in suspensions.

Photosynthetic products were separated by two-dimensional paper chromatography in phenol/water (100 : 40) followed by *n*-butanol–acetic acid–water (75 : 20 : 50)[9] or by one-dimensional high voltage paper electrophoresis in pyridine–acetic acid–water (4 : 6 : 490) buffer (*p*H 4·5)[10] at 4 kV for 30 min. Positions of radioactive products, revealed by autoradiography, were compared with those of authentic compounds detected using spray reagents. The largest radioactive areas on the electrograms were eluted and the identity of the substances established by co-chromatography and co-electrophoresis with authentic compounds.

As expected, PGA and DHAP were the major radioactive products recovered in extracts of chloroplasts which had been illuminated in suspensions (Fig. 1). In contrast, the amounts of these early intermediates of the PCR cycle produced by chloroplasts which had been illuminated on solid supports were significantly lower. More than 85 per cent of the radioactivity incorporated into ethanol soluble compounds was recovered in hexose monophosphates and amino-acids. About 10 per cent of the total carbon fixed was incorporated into a glucan (starch). These chloroplast preparations did not form sucrose. It has been suggested[11] that an enzyme concerned in the conversion of triose phosphate to hexose monophosphate controls the biosynthesis of sucrose in isolated chloroplasts. It might therefore be expected that the accumulation of monophosphates by chloroplasts illuminated on filter paper disks would favour sucrose formation. Because sucrose was not formed, however, it seems that the factors controlling its biosynthesis are more complex.

Book Reviews

TYING THINGS TOGETHER

Systems Psychology

Edited by Kenyon B. de Greene. (McGraw-Hill Series in Management.) Pp. xviii + 593. (McGraw-Hill: New York and Maidenhead, July 1970.) 178*s*.

THIS is an expensive book but it is a large one—about 400,000 words long. There are fifteen authors, all American, who are mostly psychologists but a few engineers and administrators are included. They deal with topics such as systems analysis techniques, accidents and safety, control systems, man–computer interrelationships, psychophysiological stress and "esthetics, architecture and city and regional design". The writing is discursive, usually factual, sometimes tedious, sometimes emotional and is rather deceptively informal. Deceptive in that there is an enormous expertise and a quality of structured thinking which may not be obvious to the reader who has not tried to do this kind of work. The authors are clearly men of extensive experience in the design of large scale systems, and many have a background of laboratory experimental work with which they tend to be disillusioned. For example, Chapanis (p. 76), "the fact of the matter is that most laboratory experiments in psychology have only very limited relevance for the solution of practical problems".

Systems psychology emerged from experiences on the post-war defence systems such as SAGE. This book is an advance on earlier ones in that it includes extensive work on space systems such as Apollo, industrial problems of computer based information systems and some tentative and entirely speculative excursions into current social problems. Typically the systems approach is defined as "a pragmatic approach to tying things together" justified by a rather nice quotation from John Muir, "When we try to pick out anything by itself we find it hitched to everything else in the universe". There are various dimensions and hierarchies of systems: behavioural—biological—equipment, particles—atoms—molecules—colloids—nuclei—cells—tissues—organs—organisms—man–machine systems—groupings, parts—units—components—subsystems—systems—macrosystems, elements—tasks—duties—jobs, automatic—man–machine—socio-technical—social. The systems psychologist is the specialist in human behaviour within this structure; he is the advocate for the human operator particularly when there is arbitration about the relative roles of men and machines. He functions most effectively as a member of design and development teams especially for technologically advanced systems. His tools are chiefly those of systematic observation, recording and analysis of real behaviour: task analysis, skills analysis and error analysis. He occasionally resorts to the study of isolated variables in the laboratory situation but only as a source of supporting evidence for his systematic observation. For the conduct of experiments he more often uses a simulator where the operator's task and environment are as similar as possible to "reality". He believes in training but seems to need the superficial security of hardware dominated training which relies on computers, simulators, teaching machines, mock-ups and visual aids: the teacher has become either a "management developer" or a "lesson planner". His more formal concepts are mathematically based: information theory, decision theory and control theory. He tries to steer a difficult course between the need to be comprehensive in his consideration of relevant variables and his preference for hard evidence. His justification must be that no more than a fair share of real system failures result from his design mistakes.

The book brings us up to date on current practice. There are interesting but dangerous new trends in the recognition of social problems and the substitution of humanistic values for cost effectiveness—dangerous in that the systems psychologists have at present no more idea of how to tackle these problems than anybody else has. The sweeping nature of systems concepts has an unfortunate tendency to induce grandiose thinking. In common with every other scientist or technologist, the systems psychologist can only deal with problems in relation to which he has both relevant concepts and relevant evidence. The interesting question is whether a young psychologist can operate more effectively as a laboratory experimentalist or a systems designer. My vote goes to the latter. Not because laboratory work is necessarily invalid but rather because the advancement of knowledge by good laboratory experiments is just too difficult except for a very tiny minority of research workers. Systems design is also difficult but those who are not sufficiently competent are more easily found out.

The book lacks an author index. References are placed at the end of each short chapter and so its value as a guide to the literature is not high. Diagrams and tables of data are excellent but there are not enough of them.

W. T. SINGLETON

RECORDS OF IRON-AGE HORSEMEN

Frozen Tombs of Siberia

The Pazyryk Burials of Iron Age Horsemen. By Sergei I. Rudenko. Translated from the Russian and with a preface by M. W. Thompson. Pp. xxxvi + 340 + 180 plates. (Dent: London, September 1970.) 252*s*.

PROFESSOR Sergei Ivanovich Rudenko was born in 1885. He graduated in Leningrad and was until his recent death a senior scientific member of the Institute of Archaeology of the Russian Academy of Sciences. Primarily an anthropologist, he readily appreciated that in Siberia the primitive present was very close to the primitive past. In 1947–9 he excavated four large barrows at Pazyryk. Frozen barrows had been dug in the Altai by Radloff in 1865, and by Gryaznov in 1925–9. One of Gryaznov's barrows was Pazyryk 1. No further work was carried out until 1947–9 when the other four large barrows at Pazyryk were excavated by Rudenko. It is the work at Pazyryk in 1929 and 1947–9 that formed the subject of Rudenko's *Kultura Naseleniya Gornogo Altaya v Skifskoe Vremya* published in Moscow/Leningrad in 1953. This present book is an English translation by Dr M. W. Thompson, and has the benefit of revisions by the author. The results of excavations since 1949 in other barrows in the Altai, where the finds were far less spectacular than those in the five Pazyryk barrows, were published by Rudenko in 1960 in his *The Culture of the Population of the Central Altai in Scythian Times* (Moscow/Leningrad), together with some revised judgments on his earlier work.

The dead in the Pazyryk barrows were buried in wooden chambers in shafts below the mounds. The unusual preservation of materials and human bodies from the ancient and prehistoric past of man is one of the great fascinations of the archaeological record. No student of the past can fail to be excited by the bodies surviving in the tree-coffins of Denmark or by discoveries such as those of Tollund and Grauballe man in the Danish peat bogs. Great dryness or wetness can preserve human beings, leather, wood and textiles as we know from Europe and America, but in a limited area of Asia—Mongolia and Siberia—constant freezing has the same spectacular results.

In the five great Pazyryk barrows the peculiarity of construction, the climate and the altitude caused the contents to freeze up after burial. Subsequently, robbers broke into these tombs, just as robbers have broken into allegedly rich tombs in Egypt and elsewhere; they took away much of the contents, but they never got to the accoutred horses outside the burial chambers. The skins of these horses survived intact and show us their colours and breeding. The condition of the human bodies was so good that it is possible to study the tattooing and to make one wonder again whether classical writers, describing the ancient Britons, were describing painting in woad or Pazyryk-like tattooing.

The artefacts of bone, wood and horn are remarkable as one might expect from the graves of important persons. There were found many bridles and saddles as well as an elaborate carriage. Perhaps the most exciting finds were pieces of Chinese silk, a Chinese mirror and a Persian carpet and a complete apparatus for inhaling the fumes of Indian hemp.

In his preface Thompson writes "the refrigerated objects . . . not only throw a flood of light on aspects of the life of the people who used them which have normally left no trace: but also throw some light on the civilized areas with which these people were in contact: the Persian and Chinese textiles at Pazyryk are older than any surviving examples in Persia or China".

These were the tombs of semi-nomadic people, pastoral ancestors of the Kazakhs and other peoples who lived from the Caspian to the Altai mountains: people who practised little cultivation but kept herds of horses, cattle, sheep and goats. Carbon-14 dating tells us that these barrows date from between 500 and 200 BC: possibly 400 BC is the most likely date.

This is a remarkable book and we are fortunate in having it available in English in such a lavishly illustrated form. Dr Thompson has not only done the translation but contributed a long and learned introduction that is itself a most valuable essay. GLYN DANIEL

EVOLUTION AND GENETICS

Evolution and Genetics in Honor of Theodosius Dobzhansky

Edited by M. K. Hecht and W. C. Steere. Pp. xv + 594. (North-Holland: Amsterdam; Appleton-Century-Crofts: New York, 1970.) 152*s*.

Evolutionary Biology

Vol. 3. Edited by Theodosius Dobzhansky, Max K. Hecht and William C. Steere. Pp. viii + 309. (North-Holland: Amsterdam; Appleton-Century-Crofts: New York, 1969.) 147*s*.

THE inevitable *festschrift* for Dobzhansky has appeared; it is a handsome book with fifteen articles on evolution and genetics and an introductory chapter about Dobzhansky himself. With what trepidation must honoured academics first open the pages of their *festschrift*, scan the titles, and start to read. Will the papers be irrelevant to their life's work; will they be rehashes of previous tired reviews; or will the papers be there simply because they will not be critically refereed ? (One has seen them, unfortunately.) The famous must have some tense moments.

Dobzhansky's admirers have, on the whole, done him well. Naturally, most of the articles are reviews. Two are historical or philosophical. The essay by Simpson, on "Uniformitarianism", is a delight to read. Rensch's article on "Panpsychistic Identism" is almost completely opaque, but there are signs that the translation is very unhelpful. The reviews are often long, and can treat the subject to a satisfying depth. In particular, the paper by Carson, Hardy, Spieth and Stone (100 pages long) is fascinating. There are four other reviews on aspects of *Drosophila*. Beardmore discusses the relationship between the variability of the environment and the variability of gene pools. Spiess gives a long review of the influence of the genotype on mating ability in *Drosophila*. Brncic discusses Chilean *Drosophila*, and it is interesting to compare the relatively staid evolution of these drosophilids with the florid evolutionary behaviour of the Hawaiian forms. Ayala deals with Volterra's equations in relation to competition experiments with *Drosophila*, and he attempts to discern the effects of competition on the genotype.

Stebbins discusses the progress in plant evolutionary studies since his book was published in 1950. The article by Li on human genetic adaptation, though a useful summary, is somewhat too slight to be very satisfying, but it is amusing reading, particularly for the way he can dispose of opponents with a deft phrase. Two papers, by Florkin and Schoffeniels on adapted molecules, and by White on parthenogenetic animals, complete the reviews. The former paper is extremely slight.

Creed, Dowdeswell, Ford and McWhirter have nearly brought up to date their studies of the peculiar "boundary phenomenon" in *Maniola jurtina*. Although some interesting thoughts spring from their paper, it is frustrating not to have a clue as to what selective forces are working on the species. Eiche and Gustafsson report on a massive experiment to determine the hardiness of Scots pine transplanted to more or less climatically unfriendly sites in Sweden. The writers, and the reader, are troubled at times by the interaction of climatic and inbreeding effects. The Rizkis report some peculiar patterns of enzyme activity in *Drosophila* species hybrids. Finally, Wallace, in a short paper, astonished the non-drosophiliac reviewer with the very small distances *Drosophila* feels it necessary to move if conditions are right.

All in all we have here a solid, reasonably digestible mass of the kinds of evolutionary study that Dobzhansky and the rest of us will appreciate.

The other book is the third volume of a series edited by Dobzhansky, Hecht and Steere. So far, this series has been a useful one, with a good range of topics. Here there are articles on aspects of evolution in oats, social bees and parthenogenetic weevils. The article on defences against visually hunting predators is interesting but it is rather out of place. Other articles cover sexual selection in *Drosophila* and cancer cells as temperature sensitive mutants, and, finally, there is a long and welcome article by Hopson and Crompton in which they argue for the monophyletic origin of mammals. J. D. CURREY

THE *DROSOPHILA* OVARY

Ovarian Development in *Drosophila melanogaster*

By Robert C. King. Pp. x + 227. (Academic: New York and London, July 1970.) 154*s*.

Drosophila melanogaster is probably the commonest experimental animal, and the literature on it increases by more than two papers a day. Most of this output is concerned with genetics, of course, and there is still a surprising shortage of publications on *Drosophila* physiology, even reproductive physiology. Professor King's book is therefore very welcome because it fills one such gap by dealing with the important subject of ovogenesis. In essence, it is a summing up of the researches carried out or stimulated by his group during the past fifteen years, and anybody familiar with this work will expect this monograph to be well illustrated with clear line drawings and by relevant photomicrographs; their expectations will be fulfilled. This book will therefore be useful as a convenient standard reference; others will find it a useful review of muscoid ovogenesis, as typified by *Drosophila*. The skeleton of the subject is necessarily descriptive morphology, covering everything so far published

from the origin of the pole cells to the mature, functioning organ. This anatomical detail is extensively illustrated. But the text is also an essay in developmental genetics, for the advantage of *Drosophila* is that mutants are available which interfere with normal processes and thus provide comparative material for experimental study.

Not all the general problems of morphogenesis are subsumed in the ovary, but a large number are: from the origins of polarity in the undifferentiated larval rudiment, through the many problems of stem cells, the exact regulation of division of their products to form 16-cell cysts and the differentiation of all but one of these cells into polytene nurse cells, to cell interactions and to the hormonal initiation of egg production and the regulation of egg output. All of these are discussed, but only a few mutants affecting some morphogenetic events have so far been found and can be examined. This book should stimulate the search for more. Using female sterile mutants (*fused*, *female sterile* and *narrow*) it has been possible to show, for instance, that each gene affects the restriction of cystocyte division, leads to the development of "tumorous" cysts, and acts autonomously. King produces a molecular model to explain this, which he recognizes is too speculative but which may be a useful working hypothesis. Similarly, he uses crossover suppressor mutations to examine the cytology of the oocyte nucleus, and shows that synaptonemal complexes are not then formed. This leads to an extensive discussion of recombination, and to further models. The effects of other mutants influencing vitellogenesis, development of follicle cells and of nurse cells are also indicated, and the book concludes with a short section on interactions of the ovary with other organs. Unfortunately these interesting analyses throw little light on the major problem of relating the detailed events of ovogenesis to embryonic determination in this mosaic egg.

In some respects too much material is compressed into too little space, and the book is far too expensive for its size. But it is a mine of information, covering about 500 references, and it should stimulate further work, as intended. There is a comprehensive index.

JAMES H. SANG

ORGANELLE DEVELOPMENT

Control of Organelle Development

Edited by P. L. Miller. (Symposia of the Society for Experimental Biology, No. 24.) Pp. viii+524. Published for the Company of Biologists on behalf of the Society for Experimental Biology. (Cambridge University: London, October 1970.) 140*s*.

ALTHOUGH the non-chromosomal transmission of mutations involving chloroplast and mitochondrial functions had been studied for many years, it is only in the past decade, following the discovery that these organelles contained DNA and were capable of incorporating labelled amino-acids into their proteins independently of the cytoplasmic ribosomal systems, that a combined assault by biochemists, cytologists and geneticists on the problem of organelle development has been sustained.

It is difficult to point to the major contributions made by individual authors in this volume because many contributors have attacked the problems across a broad front. Overall, however, a coherent picture of the influences involved in the assembly of chloroplasts and mitochondria emerges. Their DNA, RNA and protein synthesizing systems are shown to resemble the corresponding systems in bacteria and reinforce the idea, favoured by a number of contributors, that these organelles have evolved from endosymbiotic prokaryotes. It is made equally clear that the degree of autonomy of chloroplasts and mitochondria is limited and that nuclear genes provide considerable information for the structure of the organelles and control of their assembly. Even the nucleus enjoys only a limited autonomy for its activities are shown to be influenced by the status of the cytoplasm.

Three contributors describe their work on recombination of chloroplast and mitochondrial genes. Of particular interest in this respect is the suggestion by Slonimski and his co-workers that, in yeast, the tendency for mitochondrial genes to undergo recombination depends not only on their separation, but also on their distance from a polarity locus which may vary from strain to strain. This implies a kind of mitochondrial sexuality, possibly independent of the cell mating type.

On the whole, the contributions maintain the high standard set by previous symposia organized by the Society for Experimental Biology and the book provides a more comprehensive approach to the field of organelle development than has been previously achieved.

PETER A. WHITTAKER

PLANT VARIETIES

Genetic Resources in Plants

Their Exploration and Conservation. Edited by O. H. Frankel and E. Bennett. (IBP Handbook No. 11.) Pp. xxi+554. (Blackwell Scientific: Oxford and Edinburgh.) 100*s*

THIS book, published in the IBP Handbook Series as a guide for biologists participating in international programmes, includes the papers presented during an FAO/IBP technical conference held in Rome in 1967. It is divided into six sections. The first deals with the evolution of cultivated plants and includes descriptions of the pattern of genetic variability and of adaptation in cultivated plant populations. This is an extremely useful section emphasizing important concepts and principles. This subject leads on to the tactics of plant exploration and to the ecological considerations involved. The third section describes the methods of exploring variability in individual crops and forest tree species and is rather inadequate in that no crop is dealt with fully. Section four includes the evaluation and utilization of genetic resources, and chapter 37 by Krull and Borlaug stresses an important point that effective utilization of variability in breeding improvement depends on breeding to a well defined objective. The final sections, on documentation and conservation, contain information which is new. The methods suggested for the conservation of genetic resources include the management and provision of an inventory of wild communities or primitive cultivars, the maintenance of plant introduction collections at breeding stations, world seed banks and the development of composites or mass reservoirs of variability. Because there is no practical way in which plant material can be maintained with complete genetic integrity, any of these methods must be a compromise and the problems of maintenance of variability are clearly discussed by Allard in chapters 8 and 41. Although the conservation of variability is important it would be quite impossible to conserve all the variability that now exists and the plant breeder could never utilize all this variability. Effective utilization of variability by the plant breeder must be emphasized; so often genetic advance is not limited by variability but by the selection pressures to which the organism is subjected.

This book with its 554 pages and more than forty contributors is not recommended for consumption in one sitting but rather as a book to be dipped into like an encyclopaedia. As such, it provides a most useful source of information not available elsewhere; the editors and contributors have succeeded in stimulating thought and possibly action on this world wide problem of the conservation of genetic resources in plants. A. M. EVANS

ELECTROCHEMICAL PROCESSES

Electrochemistry

By J. Koryta, J. Dvorak, and V. Bohackova. Pp. xv+350. (Methuen: London, September 1970.) 105*s*.

TEXTBOOKS and monographs on electrochemistry are fairly common but here at long last is one that can be recommended. The material for the book originated in lectures given at the Charles University in Prague. The four principal chapters deal with equilibria in electrolyte solution, transport phenomena, equilibria in heterogeneous electrochemical systems and the kinetics of electrochemical processes.

Although first year undergraduates might find the going rather tough, the level is suitable for a third year course or for postgraduates starting on electrochemical research. For instance, there are useful sections on such topics as the acidity function, convective diffusion and experimental methods in electrochemical kinetics; there is also a valuable discussion of the double layer, and the authors quite rightly devote as much space to diffusion as to conductivity in electrolyte solutions. There is necessarily a large number of equations but the mathematics is well explained and there is a useful appendix on the solution of the differential equations found in electrochemistry. The authors' descriptions are concise and they certainly believe in using the deep end: the Debye–Hückel theory starts on page 17 and the pace continues to be as fast. But the topics are ordered in a logical rather than in a traditional or historical fashion.

The standard of the English is good and there are plenty of helpful diagrams. One can criticize one or two small points; for instance, there is only just over a page on the actual measurement of activity coefficients and the examples of important electrode processes are too briefly described. I would have preferred more references than the twenty or so key review articles given at the end of each chapter. But all in all this is a book to be recommended for teachers and students. Professor Koryta and his co-authors will now have to get busy re-writing the book in SI units, no doubt a more difficult task than translating it into English.

W. J. ALBERY

RADIATION CHEMISTRY

The Radiation-induced Decomposition of Inorganic Molecular Ions

By Everett R. Johnson. Pp. ix+144. (Gordon and Breach: New York and London, August 1970.) 145*s*; $17.40.

I DID not immediately comprehend from the title that this was a book about the chemical effects of high energy radiation on inorganic solids. At a first glance and even on reflexion it is easy to confuse the stable molecular ions of this book with the transient molecular ions which have little or no connexion with the subject matter of the book. Indeed, the investigation of such transient molecular ions, both positive and negative, constitutes one of the most active areas of chemical physics at the present time. Workers in this field would certainly feel cheated if they bought this book, and in any future edition it would certainly be advisable to select a less ambiguous title.

Title apart, the book is most useful and presents in a most readable manner the chemical changes induced by ionizing radiations in inorganic solids such as nitrates, chlorates, perchlorates, bromates, azides and permanganates. An introductory chapter gives certain background material in solid state chemistry, and this is followed by a general account of the factors affecting the radiation decomposition of inorganic solids. Thereafter, the solids are discussed individually according to the nature of the anion. The account is both descriptive and critical and the book can be recommended to graduate students who are freshly entering the field. The subject, which has not progressed far beyond the descriptive stage, is still fraught with inconsistencies and remains removed from the main stream of chemistry. Nevertheless, the author has made a determined and praiseworthy attempt to systematize the available data. The major limitations are inherent in the subject itself.

GLYN O. PHILLIPS

WORK OF A MASTER

Gesammelte Abhandlungen

By David Hilbert. Second edition: Band 1: Zahlentheorie. Pp. xvi+539. Band 2: Algebra, Invariantentheorie, Geometrie. Pp. viii+453. Band 3: Analysis, Grundlagen der Mathematik, Physik, Verschiedenes, Lebensgeschichte. Pp. vii+435. (Springer-Verlag: Berlin and New York, 1970.) DM98; $27 the set.

THE firm of Springer has given us, in the same year as Constance Reid's excellent life of Hilbert, a reprint of the master's collected papers, first published in 1932–5. It would be an exaggeration to say that these papers cover the whole field of mathematical development in the half-century 1885–1935; for instance, Hilbert seems to have had little interest in the Lebesgue theory. But nobody else of the time could match his power of making deep and fundamental penetrations on so wide a front.

Arrangement is not chronological, but by topics. The first volume deals largely with his series of great memoirs, establishing the principles of class field theory. It ends, however, with a dessert dish in the proof of Waring's conjecture; the first note in 1909 used a 25-ple integral, but the second note in the same year made a 5-ple integral suffice. In the second volume, we find the three pages in which Hilbert disposed of Gordan's theorem on the existence of a finite basis for invariants, a proof which provoked Gordan to remark "This is not mathematics, this is theology". The whole contents of this volume are set in perspective by two surveys, one by van der Waerden on the algebraic part, and one by Schmidt on the geometric work, principally the axiomatic formalization of geometry.

Volume three is a rich miscellany. The papers on analysis deal chiefly with the rehabilitation of Dirichlet's principle, and some axiomatics. Then there is the famous paper given to the international congress in Paris in 1900, the list of unsolved problems which governed the direction of much of twentieth-century mathematics. The memoirs on integral equations, later collected into a book, are not included, but there is a most valuable survey of this topic, up to and including Hilbert's powerful contributions, by Hellinger.

The volumes have been printed with the publisher's usual care and skill, and any library with mathematical pretensions, however meagre, must find room for them.

T. A. A. BROADBENT

REVISED KUHN

Atomic Spectra

By H. G. Kuhn. Second edition. Pp. xvii+472. (Longman: London, January 1970.) 105*s*.

THE publication of a second edition of *Atomic Spectra* indicates that the book has found its place in the physics literature in that it covers the subject more thoroughly than the more general textbooks while being less mathematical than the more specialized texts such as that by Condon and Shortley.

For some years now the principal trend in high resolution atomic spectra has been the use of radio frequency

methods where very small level differences can be more easily and accurately measured; some 15 pages have therefore been added to the first edition covering such topics as atomic beam resonance and optical pumping. As might be expected from the author's interests, the sections on width and shape of spectral lines have also been increased with a discussion on Voigt profiles following recent work. Recent developments in the field of auto-ionization have also been included. Basically the book remains as in the 1962 edition—an excellent summary of the theoretical interpretation of atomic spectra, with hyperfine structure and isotope shift being most thoroughly treated. The omission of even a passing mention of applied spectroscopy, either in the spectrochemical aspects or its use in astrophysics, for example, solar corona and ultraviolet spectra (see the work on the solar eclipse described in *Nature*, **226**, 229 and 1097; 1970), emphasizes the academic outlook. The book will continue to prove most useful for the more advanced undergraduate and the research worker both in the title subject itself and related fields where interpretation of spectra is essential.

L. Bovey

AIR POLLUTION MEASUREMENT

The Analysis of Air Pollutants

By W. Leithe. Translated by R. Kondor. Pp. x+304. (Ann Arbor–Humphrey: Ann Arbor and London, July 1970.) $18.75.

This book is a translation of the original German edition of 1968. In this English edition is included the author's addenda (11 pp.) giving additions and bibliographic references which apply in particular to British and American conditions.

The book is divided into six parts. The first is a discussion on the problems of clean air. History and legislation are considered as well as sources and control of pollution, meteorological effects on dispersion and the hygiene of air pollutants. In the space available these aspects can be but briefly summarized. Regulations operative in German-speaking countries predominate and proposed values of maximum ground level concentrations, are the MIK-values of the Union of German Engineers. The addenda relating British legislation is disappointing. The work of the Alkali Inspectorate is noted and the Clean Air Act (1956) is briefly—and incorrectly—summarized in six lines. More recent legislation is not mentioned.

The next two parts deal with special techniques for air sampling and for preparation of gaseous mixtures of known composition. These are most useful sections, the techniques being most clearly described. The fourth part considers special analytical methods. A selection of apparatus specifically designed for estimation of pollutants, from the simple Dräger tubes to sophisticated automatic continuous devices of British, American and German manufacture, is described. The generous treatment of gas chromatographic methods of pollution measurement is particularly interesting.

The last two parts (which account for more than 50 per cent of the book) contain a selection of methods for the estimation of all types of pollutants. The working procedures are described with typical Germanic thoroughness and attention to detail. All methods are supported by an extensive bibliography. (The bibliography contains 327 entries and an additional 88 references are listed in the addenda.) It is disappointing that the Warren Spring method for the estimation of smoke—as used in the British National Survey—is omitted but, in any selection, one expects to find certain personal favourites excluded.

Overall, the work should prove to be a vade mecum for the analyst engaged in any aspect of pollution measurement.

Frederick J. Allan

Short Notices

World Nuclear Directory.

Fourth edition. Pp. lxxix+764. (Harrap: London, November 1970.) 300*s*.

The latest edition of this comprehensive reference book remains basically an international list by countries of bodies concerned with the study and exploitation of nuclear phenomena. The entries under the name of a particular country are divided into subgroups such as national agencies, government departments, universities and industrial concerns; each entry gives a short account of the nuclear activities of the body or institution with its address and the names of its chief personnel (in most cases). One of the principal additions is a list of reactors throughout the world, with their commonly used abbreviations or names and their state (under construction, proposed or dismantled, for example). A list of world nuclear periodicals and their editors or editorial boards is also included. The book can be slightly criticized on the grounds that the subgroups run on from one to the next without distinction. It is possible that a reader unfamiliar with the layout and not using the index might look in the wrong subgroup because each is listed alphabetically.

X-rays.

By Brian Bowers. (A Science Museum Booklet.) Pp. 36. (HMSO: London, 1970.) 4*s* 6*d*.

This booklet is primarily a history of the development of X-rays and an account of their everyday use in such diverse applications as medicine, materials testing and the study of painting. As a Science Museum booklet, it begins predictably enough with a brief survey of the museum's own collection of X-ray equipment and early radiographs. The booklet commends itself to sixth formers and to students about to visit the museum, and indeed to anybody, specialist or not, interested in an overall picture of the growth of the subject. One unusual feature of the publication is a description of popular attitudes to X-rays soon after their discovery at the end of the last century; a New York newspaper, for example, announced that X-rays were being used "to reflect anatomic diagrams directly into the brains of the students, making a much more enduring impression than the ordinary methods of learning anatomic details".

Non-Solar X- and Gamma-ray Astronomy.

Edited by L. Gratton. (International Astronomical Union Symposium No. 37, Rome, Italy, May 8–10, 1969.) Pp. x+425. (Reidel: Dordrecht, 1970.) Hfl. 70.

Over the past eight years high energy astronomy has become an important source of information about the universe. The expected launch in 1971 of a satellite devoted exclusively to high energy astronomy should, if successful, provide more information each day than has so far been gleaned by all the balloon and sounding rocket experiments. This, then, is a good time to take stock of the situation in high energy astronomy. The symposium held in Rome in 1969 achieved just such a stocktaking, and the publication of its proceedings provides a landmark in the development of the topic. Observations are, in general, not yet sufficiently definitive for detailed theories of the sources to be constructed, but reviews of the theoretical position as of 1969 are very complete, so that anybody working in the field of high energy astronomy would need little more than this volume and those papers published since mid 1969 in order to place his own work in perspective. When so much has already been achieved with limited techniques the potential of the X-ray Explorer satellite is awe-inspiring; this may well be the last opportunity for any normal individual to have any hope of achieving a widespread knowledge of the whole field.

Correspondence

Citation Idiosyncrasies

SIR,—In continuing the discussion on the use of the Science Citation Index for historical purposes, Mr Cawkell is undoubtedly right in arguing that it is necessary to work on probabilities rather than certainties. You, sir, are equally correct in your editorial in pointing out that comparatively little is known as to why authors cite particular papers when writing an account of their own work.

In my review of the Science Citation Index for 1964 (*Nature*, **208**, 717; 1965) I made two particular points. First, that the value of the Index could only be truly assessed when volumes covering a number of years were available. That is now the situation, and it is reasonable to say that it has proved to be a useful information retrieval tool. As a generalization it can be said that, if the use of any major information retrieval system results in the retrieval of some 60 per cent of the relevant papers (for example, ref. 1), then the Science Citation Index will also be able to produce references to some 60 per cent of the relevant papers; the value of the index is that it is likely to retrieve a different sub-set and therefore the use of the two systems might well result in an increase of, say, 85 per cent in the overall recall ratio.

My second point was that an improvement in the citing habits of authors would do more than anything else to improve the usefulness of a citation index, and suggested that the time was coming when editors of scientific journals should take the same active steps to obtain a higher quality of citing as they have successfully been doing in relation to titles and abstracts. While the ultimate value of citation indexes was still uncertain, this was perhaps an optimistic hope, but the adoption of a simple code showing the purpose of a citation, for example, that it referred to a standard experimental technique, would undoubtedly increase the usefulness of the Science Citation Index. It would not, of course, result in the retrieval of a single additional relevant paper, but it would eliminate some of the noise which, *pace* Mr Cawkell's remarks, is as troublesome in the Science Citation Index as in any other information retrieval system.

Yours faithfully,

C. W. CLEVERDON

Library,
Cranfield Institute of Technology,
Cranfield, Bedford.

[1] Lancaster, F. W., *Evaluation of the Medlars Demand Search Service* (National Library of Medicine, Washington, 1968).

SIR,—The recent correspondence in *Nature* on the importance or otherwise of having one's papers cited extensively and the alleged structure of scientific development which can be perceived in a citation index has led me to wonder whether reference giving has not become an absurd convention which scientists unthinkingly adhere to. I claim no special virtue of freedom from infection in this respect.

To the outsider, the scientific referencing system must seem burdensome, pompous and irrelevant. What is the purpose of giving a reference? We answer that it allows the reader to enter a new field by giving him background, that it establishes the truth of our assertions and it enables us to indicate the extent of our own original contribution. Our rationalized view of reference-giving seems to me about as relevant to what really happens in science as the philosopher of science's concern with induction, deduction, hypothesis theory and law. The process of giving a reference is frequently wayward, dishonest or self-centred. We are fairly well constrained to tell the truth so all our pent-up human instinct to self aggrandisement comes bubbling to the surface in those first few paragraphs where we tell it "like it is". In that fertile ground we can tell you how we had the idea first—"The recent interesting proposal of Doe *et al.*[1] comes as a gratifying confirmation of my earlier ideas[2]", where it turns out that reference (1) is a full mathematical analysis with several experimental examples whereas (2) is the abstract of a speculative paper read to the Bruddesford Philosophical Society in which we managed to cover all possible developments in half an hour of arm-waving. Or we can tell you how extraordinarily well read we are, by quoting fifteen peripherally relevant articles in fifteen languages. Most of these articles will have been accumulated by accretion. Someone else referred to them and we added them to our list because they looked nice. This illustrates a fundamental law of reference giving—*it is quite unnecessary to have read or even seen the reference yourself before quoting it.*

Or we can show how up-to-date we are with all our references being not more than two years old. Or we can show how well connected we are by giving references to a large number of preprints. Or we can discreetly kick someone in the teeth by omitting to refer to his relevant paper. This last procedure guarantees us a large manilla envelope in the mail a few weeks later with his reprint inscribed with compliments. Or we can show our contempt for modern science by referring only to textbooks printed before 1900. Or we can spike criticism by a glowing reference to a potential critic. Or (the most common of all) we can take out our box of well-worn cards, shuffle them, xerox them and stick them on the end of the paper. "A mere orgy of dittography" as Evelyn Waugh's headmaster once criticized one of his essays. But we must be careful to mention every reference in the text; one of the more common sub-editorial comments on galley proofs is "not mentioned in text" against references.

With such an idiosyncratic background to references why bother at all? Practising insiders know how a paper fits into the mainstream of science and references are wasted on them. The intelligent outsider, if he can ever wade through our prose, is presumably sufficiently intelligent to write to us if he wants to know more. Perhaps most persuasive, however, is the time that would be saved by secretaries, sub-editors and printers in not having to reproduce that page of staccato, italicized, underlined, abbreviated, semi-colonized non-prose. And not having to worry whether the abbreviation for "Royal" if *roy.* or *Roy.* or even *r.*

As you must be aware, sir, authors of articles in *Nature* deem it desirable to have 25 ± 10 references in their papers. By reducing references to mention of previously unnoticed papers, useful equations and proofs, papers which one takes issue with or papers of very recent vintage which need to be brought urgently to public attention this figure might be reduced to 5 ± 3. It does not seem to me that science would be impeded; some money might even be saved.

I repeat—*mea culpa, sed inter alios.*

Yours faithfully,

DAVID DAVIES

Belmont,
Massachusetts 02178.

SIR,—Alphabetical ordering of names in multi-author publication results in ambiguity about who did what; non-alphabetical ordering enhances the visibility of the individual by suggesting the order of importance of his contribution. There are no strict rules regarding assignment of publication credit among collaborators; many practices are followed[1,2]. We show that the policy by which multiple authors of papers published in *The Journal of Physiology* are listed in alphabetical order by surname without indication of the relative contributions of individuals has exerted selective control over publication of research in the journal.

The percentages of papers with different sizes of author-set published in vols 155–175 (1961–1964) of *J. Physiol.* were calculated in cases where the surname of at least one author began with A–E (520 cases) or P–Z (503 cases). Alphabetical value had no significant influence ($\chi^2 = 0{\cdot}05$, $P > 0{\cdot}05$) on whether an author published singly or with collaborators, even though in cases of multiple authorship P–Z surnames received first listing in only 7·6 per cent of cases compared with 80 per cent for A–E surnames. The possibility next considered was that P–Z authors published collaboratively in *J. Physiol.* when their authorship position approximated their research contribution but elsewhere when they wished to overcome the ambiguity in assignment of credit imposed by alphabetical ordering. The bibliographies of the 1,023 papers considered above were searched to establish the practice each set of authors had followed when publishing in journals which had no fixed policy on author-sequencing. Alphabetical ordering was maintained at a rate (78 per cent of cases) well above the value (48 per cent) obtained from a count of all references cited in *Annual Review of Physiology*, **26** (1964).

We found, however, that researchers with P–Z surnames avoid publication in *J. Physiol.* relative to those with A–E surnames. Comparison of the relative occurrence of A–E and P–Z surnames as *J. Physiol.* authors and as authors in other journals cited in bibliographies in *J. Physiol.* papers (the first 1,023 cases in vols 155–156) showed that P–Z surnames were significantly underrepresented (by 12·1 per cent) as authors of *J. Physiol.* papers ($\chi^2 = 19{\cdot}2$, $P < 0{\cdot}001$). Evidence that *J. Physiol.* authors with P–Z surnames maintain alphabetical sequencing in other publications suggests they either are junior collaborators in most research they report or prepared to publish in a manner which at face value renders ambiguous their role relative to co-authors. In latter cases there are probably many factors unconnected with publication of specific research by which this ambiguity is lessened[2].

Misconception on MIRVs

SIR,—May I comment on the statement in "Pugwash Worth its Weight in SALT" (*Nature*, **227**, 1185; 1970) that: "Although the main strategic implications of MIRVs are as a first strike weapon, they were apparently developed by the United States as a penetration aid against the sophisticated Soviet air defence system which, it is claimed, is capable of being upgraded into an ABM system". This view, or more simply that the US developed its MIRV as a response to the Soviet ABM, is nearly universally repeated by persons on all sides of the ABM debate, in and out of the US Senate. It appears to be wrong. This is documented by two pieces of Congressional testimony.

Dr John Foster, Director, Defense Research and Engineering of the US Department of Defense, gave this evidence in 1968:

"Senator Mansfield: Is it not true that the US response to the discovery that the Soviets had made an initial deployment of an ABM system around Moscow and possibly elsewhere was to develop the MIRV system for Minuteman and Polaris?

"Dr Foster: Not entirely. The MIRV concept was originally generated to increase our targeting capability rather than to penetrate ABM defenses. In 1961–62 planning for targeting the Minuteman force it was found that the total number of aim points exceeded the number of Minuteman missiles. By splitting up the payload of a single missile (deleted) each (deleted) could be programmed (deleted) allowing us to cover these targets with (deleted) fewer missiles. (Deleted.) MIRV was originally born to implement the payload split-up (deleted). It was found that the previously generated MIRV concept could equally well be used against ABM (deleted)."

Mr Laird, the Secretary of Defense, gave this evidence in 1969:

Reason for US MIRV development

"Senator Pell . . .

"Now, in connexion with the system around Moscow, the so-called Galosh, the existence of which we discovered, I think, in the early 1960s, haven't we responded to that with our MIRV program? Wasn't it the Titan MIRV at that time?

"Secretary Laird: Well, I don't believe that necessarily is the case, Senator Pell. I would like to agree with you but having worked on these programs through the years——

"Senator Pell: Much more closely than I have because you were on the Armed Services Committee.

"Secretary Laird: As much as I would like to agree with you, I can't.

"Senator Pell: You feel it is a separate response, a normal outgrowth of regular research and development.

"Secretary Laird: Yes; it was a separate response and it was something we had under development and under consideration for several years even prior to the time that we knew of the deployment of the Galosh. I would not want to mislead anyone, as much as I would like to agree with you.

"Senator Pell: But our basic reason for developing MIRV was to increase our own deterrent power, not related, in your view, then to Galosh?

"Secretary Laird: It was not related to Galosh because we started appropriating funds for the development of this program prior to the time we knew Galosh was in being. That is why I cannot respond that way to that question.

"I happen to have been involved in the appropriation process, and we were funding the research and development on the MIRV, and we knew about these possibilities and had funded work on it prior to the time that the Soviet deployment of Galosh around Moscow was discovered."

The development of MIRVs is a most important point to get straight. MIRV represents a quantum, and a critical, jump in strategic weaponry. Various US administration spokesmen, past and present, have been guilty of repeating on public occasions the common misconception as to its origin, despite the above evidence to the contrary. The wrong view has no doubt been perpetuated because it presents the development (and the deployment) of MIRV as a response to Soviet action. Post ABM, ergo proctor ABM?

It may serve a useful purpose for US administrations, both the previous Democratic and the present Republican one, to maintain this error in misunderstanding, but that is no excuse for the rest of us to follow suit.

University Politics

SIR,—I read with considerable interest the article in *Nature* of October 24 (**228**, 314; 1970) on University Politics and I would like to correct one statement. This is to the effect that "At both Universities (Cape Town and Witwatersrand) members of staff and students alike . . . talk of their Universities as liberal, but it may be significant that this attitude is not usually accompanied by a willingness to embrace modern causes such as student representation". The fact is that at Witwatersrand, student representation is a very live issue and a great deal has already been achieved in bringing it about. Furthermore, the relationship between the Students' Representative Council and the University Administration is extremely cordial and strong.

Yours faithfully,

G. R. BOZZOLI

Vice-Chancellor and Principal,
University of the Witwatersrand,
Johannesburg.

Obituary

Professor T. K. Walker

THOMAS KENNEDY WALKER, professor of industrial biochemistry at the University of Manchester from 1954, when the chair was established, until his retirement in 1959, died on June 29, 1970, at the age of seventy-seven. Shortly after his death a most stimulating and remarkable account of the development of his department, written by himself, appeared in *Advances in Applied Microbiology* (**12**, 1; 1970). It describes his very extensive research work, his most happy relations with his students and his contacts with numerous biochemists at home, and especially abroad, and gives a strong impression of a man happy in his work and surroundings, with a growing, but quiet, satisfaction in the progress and reputation of his department. Walker's comments on the mental outlook required by those who would journey from the domain of organic chemistry to that of biochemistry should be read by all who have followed, or would follow, the same path. An article of his on the pollution of the environment will appear shortly.

After graduating at Manchester in 1915, Walker joined Weizmann's group to work on the technical production of acetone and *n*-butanol by an organism related to Fernbach's bacillus. This entailed a period of study at the Lister Institute. His life-long devotion to microbiology arose from this early work. His interest in large-scale operations was also enhanced by two years spent at the Royal Arsenal, Woolwich. These were followed by three years' research with Lapworth at Manchester on the interaction of diazonium salts with reactive methylene groups. From 1922 to 1925, he collaborated with Pyman at the Manchester College of Technology in an examination of the bitter bacteriostatic substance in the resin of hop-cones. Extensions of this work continued at intervals until 1958.

In 1925 Walker began a study of the behaviour of carbohydrates and aliphatic acids in cultures of *Aspergillus niger* and *Aspergillus oryzae*, during which acetic, pyruvic, dimethylpyruvic and α-ketoglutaric acids were detected in cultures of *A. niger* on various substrates, and the effect of fluoride, iodoacetate and cyanide was examined. He was frequently consulted about bacterial infections in yeast and beer and so arose a long series of investigations, many of considerable importance, on *Candida*, *Acetobacter* and *Lactobacillus* species. He became a recognized authority on *Acetobacter*, some species of which were shown to produce cellulose. From 1948 to 1958 he directed, for the Medical Research Council, extensive work on the production of edible fat by mould fungi, in which the cultural conditions for the most suitable moulds and the composition of the fat were closely studied.

Walker's manner was always quiet, friendly and unruffled. His sympathetic and encouraging attitude to the problems of young research students caused him to spend much time at their benches. He thus imparted that "feel" for the contents of a test tube or of an unpromising mixture which is the secret of successful laboratory manipulation and is still the distinguishing mark of the organic chemist. He had many diverse interests, including poetry and philosophy, and a religious faith that deepened with the lapse of years.

Announcements

University News

Professor Frank Press has been appointed Robert R. Shrock professor of earth and planetary sciences at the **Massachusetts Institute of Technology.**

Dr L. Mirsky has been appointed to a personal chair in the Department of Pure Mathematics, **University of Sheffield,** and the title of visiting professor in botany has been conferred on **Professor R. F. Jones,** State University of New York at Stony Brook, for the period January 1 to August 31, 1971.

Appointments

Professor Zdzislaw L. Wilhelmi, head of the Department of Nuclear Physics in the University of Warsaw, has been appointed director of the Division of Health, Safety and Waste Management in the Department of Technical Operations, **International Atomic Energy Agency.**

Miss Julia Henderson, associate commissioner for technical cooperation in the United Nations, has been appointed secretary-general of the **International Planned Parenthood Federation,** in succession to the late **Sir David Owen.**

International Meetings

February 18, 1971, **Safety in Chemical Manufacturing,** London (Institution of Chemical Engineers, 16 Belgrave Square, London SW1).

March 3–5, 1971, **Environment and Cancer,** Houston (Mrs Jane Brandenburger, M. D. Anderson Hospital and Tumor Institute, Texas Medical Center, Houston, Texas 77025, USA).

April 22, 1971, **Freshwater Biology and Electrical Power Generation,** Leatherhead (D. S. Wilson, Central Electricity Research Laboratories, Kelvin Avenue, Leatherhead, Surrey).

June 27, 1971, **Improving the Utilization of Energy,** with Special Reference to Complex Uses, Bucharest (The Secretary, British National Committee, World Energy Conference, 5 Bury Street, St James's, London SW1).

July 7–9, 1971, **Science and the Arts,** Edinburgh (Dr Eric G. Forbes, Institute for Advanced Studies in the Humanities, 12 Buccleuch Place, Edinburgh EH8 9LW).

July 7–9, 1971, **The Structure of Matter,** Christchurch (B. G. Wybourne, Department of Physics, University of Canterbury, Christchurch, New Zealand).

September 5–12, 1971, **Conference of Women Engineers and Scientists,** Turin (Dr A. E. Anour, Corso Vinzaglio 14, 10121 Torino, Italy).

September 6–9, 1971, **Physics and Chemistry of Asbestos Minerals,** Louvain (Mr B. Lincdn, Turner and Newall Asbestos Fibre Laboratory, c/o TAC Construction Materials Ltd, PO Box 22, Trafford Park, Manchester M17 1RU).

September 6–10, 1971, **Atomic Masses and Fundamental Constants,** Teddington (Dr B. W. Petley, Division of Quantum Metrology, National Physical Laboratory, Teddington, Middlesex).

September 6–11, 1971, **Metal-Insulator Transition and the Development of Narrow Energy Bands,** Assois (Dr A. D. Yoffe, Cavendish Laboratory, Cambridge).

September 7–9, 1971, **Computers for Analysis and Control in Medical and Biological Research,** Sheffield (Manager, Conference Department, IEE, Savoy Place, London WC2R OBL).

September 7–16, 1971, **Mycological Congress,** Exeter (John Webster, Department of Biological Sciences, University of Exeter, Devon).

September 8–10, 1971, **Oral Biology,** Zurich-Horgen (The Secretary, ICOB, Dental Institute, CH-8028 Zurich, PO Box 138, Switzerland).

September 8–11, 1971, **Drugs Affecting Lipid Metabolism,** Philadelphia (Dr William L. Holmes, Lankenau Hospital, Philadelphia, Pennsylvania 19151, USA).

September 13–16, 1971, **Cell Differentiation,** Nice (Dr Harris, Department of Medical Genetics, The Royal Infirmary, Manchester M13 9WL).

September 13–18, 1971, **Phenomena in Ionized Gases,** Oxford (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

September 14–17, 1971, **European Biophysics Congress,** Baden (Mrs E. Weidenhaus, Wiener Medizinische Akademie, Stadiongasse 6–8, A 1010 Vienna, Austria).

September 20–24, 1971, **The Urgency of Decision,** Lancaster (Conference Committee, Operational Research Society, 64 Cannon Street, London EC4N 6AD).

September 21–23, 1971, **Infrared Techniques,** Reading (Joint Conference Secretariat, IERE, 8–9 Bedford Square, London WC1B 3RG).

September 21–24, 1971, **Pneumatic Transport of Solids in Pipes,** London (H. S. Stephens, Pneumotransport I, BHRA, Cranfield, Bedford).

September 22–24, 1971, **Nuclear and Particle Physics,** Oxford (Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

September 27–October 1, 1971, **Biomechanics,** Rome (Professor Sergio Cerquiglini, Istituto di Fisiologia Umana, Università degli Studi, Rome, Italy).

British Diary

Monday, December 28

Man has a Very Short Neck and no Tail (3 p.m.) Dr. John Napier, Royal Institution, 21 Albemarle Street, London W1. (First of Six Christmas Lectures for young people on "Monkeys Without Tails": A Giraffe's Eye View of Man. Further Lectures on December 30, January 1, 4, 6 and 8.)

Tuesday, December 29

Holography and Lasers—Uses for Laser Light (2.30 p.m.) Dr W. R. Bradford, Institution of Electrical Engineers, at Savoy Place, London WC2. (Christmas Holiday Lecture. To be repeated on December 30.)

Monday, January 4

Computational Techniques as an Aid in Physical Metallurgy (two day meeting). Iron and Steel Institute, at the University of Leeds.

Thames Estuary: Restoration and Preservation of its Quality (6.30 p.m.) Dr D. Train, Society of Chemical Industry, jointly with the Industrial Water and Effluents Group, in the Scientific Societies Lecture Theatre, 23 Savile Row, London W1.

The Preservation and Waterproofing of Joinery Timber Prior to Painting (7 p.m.) Mr R. R. Hill, Oil and Colour Chemists' Association, at Hull College of Technology.

The Selection and Training of Engineers Abroad (5.30 p.m.) Mr F. H. Woodrow, Institution of Civil Engineers, at Great George Street, London SW1.

Winter Meeting, British Society for the History of Science, at Chelsea College, University of London, Manresa Road, London SW3.
